Richard Gibbs, Wofford Cain Professor, Department of Molecular and Human Genetics; Director, Human Genome Sequencing Center, Baylor College of Medicine. (2012). Ethics and Practice of Whole Genome Sequencing in the Clinic. Presentation to PCSBI, February 2, 2012. Retrieved from <http://bioethics.gov/cms/node/658>.

In the case of whole genome sequencing, as is true for many emerging medical technologies, there are tensions between some of these principles. Two of the principles—public beneficence and intellectual freedom and responsibility—support the continued pursuit of whole genome sequencing research because of the promise of intellectual gains and substantial public benefit. Simultaneously, other principles—respect for persons, responsible stewardship, and justice and fairness—counsel the adoption of protections to minimize the privacy risks that could befall individuals. Drawing upon the process of democratic deliberation, the Commission sought to reconcile the potentially conflicting practical implications of these principles. It did so by taking into account various paths to the anticipated promise of this rapidly advancing technology, while respecting the ethical concerns of the increasing numbers of individuals facing the prospect of whole genome sequencing: concerns, for example, about confidentiality, information security, decisional autonomy, and freedom from unwanted intrusion into personal lives.

The Public Benefit of Whole Genome Sequencing

Scientists predict that whole genome sequencing research will foster better understanding of the genetic factors that contribute to human health and diseases including cancer, heart disease, diabetes, and neuropsychiatric conditions, as well as many rare diseases. Further, whole genome sequencing is expected to usher in an era of personalized medicine, providing information that might allow clinicians to tailor treatments or manage the health of individuals based on their genomic profile.

The Commission's recommendations regarding the continued pursuit of whole genome sequencing to advance medical science are based primarily on the principles of public beneficence and intellectual freedom and responsibility. Public beneficence gives rise to a societal and governmental duty to promote individual activities and institutional practices, such as scientific and biomedical research, that have great potential to improve the public's wellbeing.³⁵

Public beneficence also supports scientific enterprises that advance the common good by increasing economic opportunities, a criterion that whole genome sequencing satisfies.³⁶ The U.S. government invested billions of dollars in the Human Genome Project—a collaborative research project with the ambitious goal of sequencing the entire human genome. This

investment has since generated \$244 billion in personal income and \$796 billion in overall economic impact.³⁷ In 2010 alone, the human genome sequencing projects and associated research and industry activity directly and indirectly generated over 300,000 jobs and brought in tax revenue of \$3.7 billion. While not unique to whole genome sequencing, increased economic productivity is often a positive by-product, consistent with public beneficence, of scientific and medical progress.

Intellectual freedom grants scientists—acting responsibly—the right to use their creative abilities to advance science. Creative, sustained, and dedicated intellectual exploration is an essential aspect of scientific, technological, and clinical progress. At the same time, it serves to expand our general understanding of the world.

However, both public beneficence and intellectual responsibility, the complement to intellectual freedom, caution against pressing forward with whole genome sequencing without regard to negative consequences. The principle of public beneficence requires both that public benefits be secured *and* that public harms be minimized. Likewise, intellectual responsibility calls upon all researchers and clinicians—including their staff and the institutions that support them—to adhere to the ideals of research, one component of which is avoidance of harm to others.³⁸ Pursuing whole genome sequencing without considering potential harms would violate the clear and compelling mandates of public beneficence and intellectual responsibility.

Privacy Concerns Raised by Whole Genome Sequencing

Respect for persons includes respect for the dignity and privacy of individuals. As a result, respect for privacy assumes special salience in discussions about ethics and genetics. Because whole genome sequence data provide important insights into the medical and related life prospects of individuals as well as their relatives (who most often did not consent to the sequencing procedure), whole genome sequencing poses real privacy concerns. These concerns are compounded by the fact that whole genome sequence data gathered now might reveal important information, entirely unanticipated and unplanned for, as science progresses. The potential power of the information contained in whole genome sequencing substantially raises the privacy stakes of medical information.

“Public trust is fundamental to the ongoing support of these activities and to participant willingness to actually contribute to the research. And without the participant willingness to contribute to the research, we will not move forward at all.”

Laura Lyman Rodriguez, Director of Office of Policy, Communications and Education, National Human Genome Research Institute. (2012). Presentation to PCSBI, August 1. Retrieved from <http://bioethics.gov/cms/node/749>.

Privacy and the Law

Concerns about privacy are not new; worries about the proper boundaries between self, others, and government extend as far back in recorded human history as ancient Greece and Rome.³⁹ The central role of privacy in U.S. culture and ethics is reflected in the tone of its laws. The word “privacy” does not appear in the U.S. Constitution. However, as American courts and scholars have observed, the Bill of Rights implicitly recognizes the value of privacy and

rights of privacy through provisions guaranteeing: 1) freedom of speech, freedom of religious, political and personal association, and related forms of anonymity (First Amendment); 2) freedom from government appropriation of one's home (Third Amendment); 3) freedom from unreasonable search and seizure of one's body and property (Fourth Amendment); 4) freedom from compulsory self-incrimination (Fifth Amendment); 5) freedom from cruel and unusual punishment, including unnecessarily extreme deprivations of privacy (Eight Amendment); and 6) other personal freedoms (Ninth Amendment). In addition to the Bill of Rights, the Supreme Court and state courts have marshaled the due process clause and language of "liberty" of the Fourteenth Amendment to strike down laws interfering with autonomous medical, marital, sexual, and family decision making.

"With advancing technologies it's increasingly hard to keep secret our genetic information. There's more data-sharing... but that doesn't mean that we don't have privacy interests here, it just means that we may need more explicit protections of those interests."

Sonia Suter, Law Professor at George Washington University. (2012). Presentation to PCSBI, August 1. Retrieved from <http://bioethics.gov/cms/node/748>.

A number of U.S. states have explicit privacy protection provisions in their constitutions that apply to privacy violations by state and, in some cases, private entities. The common law of some states includes a breach of confidentiality tort. Most states recognize one or more right to privacy torts, first proposed in the 1890 article "The Right to Privacy" by Samuel Warren and Louis Brandeis. This seminal article persuasively argued that courts should recognize a "right to be let alone" against unwanted intrusion and publicity.⁴⁰ Today personal injury suits can be brought alleging intrusion upon seclusion; publication of private facts; publication placing one in a false light; and appropriation of name, likeness, or identity.

The United States takes a sectoral approach to regulating privacy, which means that the United States specifically regulates privacy concerns in particular settings as they arise. In the past four decades, in response to pervasive new technologies and related business practices, state and federal authorities have enacted many statutes and agency rules protecting the privacy of data related to health, education, finances, taxes, the federal census, video rentals, lie-detection, motor vehicle records, library records, and electronic and telephonic communications. This sectoral approach means that a number of areas that have no specific laws currently do not receive even baseline privacy protections. By contrast, Europe regulates privacy comprehensively, providing privacy protections that are consistent across different types of data or information.⁴¹

The Meanings of Privacy

Privacy and associated terms, including confidentiality, anonymity, choice, and data protection, refer to related concepts. Discussions about ethics and whole genome sequencing sometimes inappropriately use these terms interchangeably. To enable clear ethical analysis in this report, we provide basic definitions of the family of privacy terms applicable to our work and map their relationships. Scholars differ in their precise definitions of the terms we use, but the language we present in this report is consistent with a general consensus view. The following definitions are meant to show how the Commission uses these terms and to help

guide future discussions regarding ethics and genetics. They should not be taken as formal arguments for precise definitions.

Restricted Access

The term *privacy* is used here (and in many ethical and legal contexts) broadly to mean states of affairs by virtue of which the accessibility of persons, personal information, or personal property is limited or restricted. What is valued as “personal,” “sensitive,” or “intimate” may be restricted by virtue of, for example, spatial distances, physical barriers, electronic passwords, social norms, or customs. In the United States and other developed societies, health information is widely considered personal, sensitive, or intimate, and genetic information especially so.

The term *informational privacy* refers generically to restricted access to information or data. “Confidentiality,” “anonymity,” and “data protection” are specific ways to protect informational privacy in the broad sense, with special relevance in clinical and health research settings.

Confidentiality is used to denote restricting access to information or data to groups of specifically authorized recipients. In the medical context, health information is often limited by custom to close family and friends and by law to health practitioners, insurers, and professional researchers. Patients and research participants may even choose to keep health conditions secret from intimate kin by deliberately concealing the information. Confidentiality is closely connected with trusting relationships. One can share private information with another person on the understanding that he or she can be trusted to keep that information secret (i.e., will not divulge it to others). Patients entrust clinicians with medical information provided that they have a “need to know,” and understanding that the clinician will keep the information confidential. In the context of whole genome sequencing, data must be kept confidential; databases must be secure and information must not be divulged to unauthorized users.

Anonymity is used to denote restrictions on access to personally identifiable information pertaining to individuals or groups, achieved through intentionally disguising or removing identifiers. A health record can be made more anonymous, for example, by removing a patient’s name, address, or social security number.

Data protection refers to measures designed to thwart deliberate or accidental disclosures of confidential or anonymous information. Health data that are electronically stored or transmitted can be protected with computer passwords and encryption. Health care providers employ technology to protect data, but ethical norms and business practices can also protect data from unauthorized access, use, and disclosure.

Autonomy

The term “privacy” has a second distinct use in ethics and law. Privacy is a rough synonym of autonomy with respect to self-regarding conduct and intimate relationships. Here, privacy denotes the absence of substantial government or other outside interference with individuals’ decisions and choices. In traditional bioethics, the “privacy” at issue in euthanasia, birth control, and consent to research is this second understanding of privacy, which involves the ability to make autonomous decisions.

We note that there are other uses of “privacy,” some health-related, that do not play a major role in this report. Seeking greater precision and focus, privacy scholars and the courts commonly qualify the term “privacy” using descriptive adjectives. Indeed, they commonly

speak of *informational privacy* in relationship to the collection, use, and sharing of information or data. They speak of *physical privacy* in relation to observing, concealing, and touching the human body, such as entering hospital rooms or respecting patient modesty. They refer to *spatial, geographical, and locational privacy* in relation to GPS and beeper technologies. They speak of *associational privacy* in relation to affiliation with like-minded people. They recognize *decisional privacy* in relation to independent decision-making. Less commonly, privacy scholars and the courts distinguish *proprietary privacy* in relation to repositories of personal identity and genetic ownership claims. And finally, they identify *intellectual privacy* in relation to interests in freedom of thought, conscience, and the right to read and access knowledge.

There is ample debate and disagreement about the value of particular privacies and the basis for laws and policies promoting or regulating each type of privacy. In this report, the Commission focuses on *informational* and *decisional* privacy as they pertain to whole genome sequencing. We use the term “privacy” in reference to both limited access to genetic information and data, and to the absence of interference with decisions about the collection, use, and sharing of genetic information. A person whose whole genome is sequenced might have both *decisional privacy* concerns (about who is permitted to decide whether whole genome sequencing data are shared) and *informational privacy* concerns about whether such data will be shared in confidence, securely, or in de-identified form.

Although the precise contours and content of privacy have changed substantially over time, with shifts in culture as well as technology, intense and widespread human interest in the protection of privacy is abiding, not only in the United States, but also around the world. Privacy protections promote a set of highly prized values. Although modern technology can facilitate unobserved and uninvited intrusions into homes, for example, what individuals choose to do in such a domain is generally valued as a matter of “privacy” and deemed legitimately “private,” unless that behavior violates particularly weighty ethical or legal limits. That is, there are constraints on what behavior can be considered legitimately private. In the inclusive understanding of what falls under the privacy umbrella we adopt here, what individuals choose to do at home is presumptively confidential, anonymous, intimate, secure, free from unwanted intrusion, and/or subject to decisional autonomy.⁴² Concern for privacy values (while additionally a means of enabling privacy at home and other vital privacies) also incorporates the increasingly elusive ideal of control over the flow of information regarding oneself, again subject to broad ethical and legal limits.⁴³

The Value of Medical Privacy

The Commission agrees that respect for patient and participant privacy can greatly benefit individuals and the general public. Under the principle of respect for persons, and for the sake of public beneficence and justice and fairness, those who collect, use, or share health data should employ practices that include confidentiality, anonymity, and informed consent to shelter clinical patients and research participants from the unwanted glare and control of others. It is important to ensure that respect for patient and participant privacy not be compromised, not only in clinical care and research, but also in the publication or archiving of medical lectures, scholarly articles, and personal papers. Medical privacy remains an important ethical principle, despite the recognition that many people voluntarily share their health information or data, including genetic information and data, and despite the practical reality that modern institutional practices presuppose that a great deal of sensitive health information can and will be lawfully shared among providers, insurers, researchers, and the government.

Medical privacy has many varieties of recognized public value. First, medical privacy encourages individuals to seek medical care. Individuals will be more inclined to pursue medical attention if they believe they can do so on a confidential basis. Practicing confidentiality assures that, in most cases, a patient can choose when to disclose an illness, condition, or genetic status. Confidentiality and anonymity enable individuals to exercise constitutionally protected liberties of autonomous medical decision-making by safeguarding information they do not choose to share because it is embarrassing or would expose them to discrimination or disapprobation.

“It just seemed safer to keep it to myself...I didn’t know what somebody would do with that information in the future...and I was very concerned about it.”

Victoria Grove, introductory vignette, referring to her decision to keep secret her positive genetic test for alpha-1 antitrypsin deficiency.

Second, medical privacy encourages frank disclosures in clinical and research settings. Individuals seeking care can be open and honest if they can trust that facts reported to or uncovered by clinicians or researchers will not be broadcast to the world at large. People are often embarrassed by symptoms, histories, and prospects of illness. Individuals concerned about discrimination, shame, or stigma have an interest in controlling the flow of information about their health. Some patients and participants believe they own personal information about themselves, especially genetic information, and should be able to control its release.

Third, if individuals believe they can decide whether to share data, information, and biospecimens under conditions of confidentiality, anonymity, and informed consent, they might be more likely to participate in research. In the context of health research, ethics committees and institutional review boards properly require researchers to protect the privacy of research participants and their medical records. Obligations of privacy may require the use of coded information rather than names or “de-identification” procedures such as data aggregation. Some have argued that researchers must publish genomic data in ways that obscure the identities of whole families. Even statistical use of individuals’ health data has raised privacy concerns, as some have argued that for cultural or social reasons individuals might have an ethical interest in the uses of data sets without personal identifiers that include data about them.⁴⁴

Fourth, alleviating the concerns about exposure and discrimination that keep patients away from clinicians enhances confidentiality, which can further the goals of health care cost savings by ensuring that patients seek early medical care rather than waiting until their conditions worsen and require more dramatic medical intervention.⁴⁵

The Commission recognizes that privacy, like most values, has ethical as well as practical limits. It is not an absolute public good. Certain diseases, conditions, and prescriptions must be reported to government to protect public health and safety. Health care providers and responsible adults are ethically obligated to report evidence of child neglect and abuse uncovered in treatment. Mental health providers have an ethical duty to warn police or potential victims of the credibly violent intentions of patients with mental illness. Situations arise in which medical confidentiality cannot be preserved because the media has a right to publish information or legal authorities have the authority to subpoena information for use in legal proceedings and investigations. Members of the military and civil servants serving in war zones may be also required to undergo mandatory genetic biobanking or testing for varied purposes.

Privacy in Whole Genome Sequencing

Currently, whole genome sequencing involves generating, storing, sharing, and analyzing large amounts of data. Although members of the public express general comfort with the idea of sharing genomic data in biorepositories, privacy ranks among participants' highest concerns.⁴⁶ Data also show that for many, privacy concerns are an important obstacle to participation in large cohort studies.⁴⁷ Although 60 percent of people surveyed said they would participate in a study that involved storing data in biorepositories, 91 percent of those potential research participants would be concerned about privacy.⁴⁸ Additional data indicate that although a large majority of survey participants trust clinicians and researchers, they are concerned that results of genetic tests could end up in the wrong hands and be used against them.⁴⁹ Most of the people interviewed following enrollment in one sequencing study indicated that their primary concern was that they be informed if there was a possibility that their data would be shared with other researchers and that it was important they maintain some control over who could have access to their genomic data. The participants wanted insurance companies and employers to be excluded from access to these data, but were comfortable with data sharing within the research community.⁵⁰

Informational and decisional privacy concerns about the unauthorized disclosure or misuse of whole genome sequence data are not only common and intensely important in the minds of potential research participants, they are also objectively linked to the potential for serious harms from such disclosure and misuse. Potential harms include the risk of lost opportunities in employment, long-term health care, disability and life insurance, loan approvals, education, sports eligibility, military accession, and adoption eligibility.⁵¹ In areas that are far less amenable to any legal protection or recourse, individuals could find themselves facing social stigma from disclosure of sensitive genomic information, and subsequent disruption of their home, family, and community life.⁵² Risks that are more internal to, and variable among, individuals include being subject to psychological harms upon learning information that can be difficult to bear, including that one has a predisposition to a disease such as cancer or Alzheimer's disease. Because whole genome sequence information directly implicates relatives, psychological harms often are not limited to the person whose genome is voluntarily being sequenced and publicly disclosed. Even individuals who learn that they do not carry a harmful variant may experience "survivor's guilt" if another family member is affected.⁵³

To date, the number of documented cases of discrimination on the basis of genetic test results is small.⁵⁴ This might be due to the relatively few conditions for which there are currently definitive genetic tests, coupled with the expense and difficulty of conducting these tests. As a result, genetic information is rarely available to third parties. Another reason for the small number of reported cases, now and potentially in the future, might be the difficulty of uncovering and documenting discriminatory use of data.⁵⁵ It is also possible that such discrimination might not occur, either because there are other more definitive bases on which to make insurance or employment decisions, or because all individuals have some form of disease predispositions. Regardless, legitimate concerns remain about the potential for differential treatment of individuals based on their genomic information, even if legally prohibited discrimination rarely occurs. If individuals lack assurances against misuse of their genomic information, their privacy concerns might motivate them to not share their whole genome sequence data, which could harm the research enterprise that generates life-saving discoveries.

Privacy and the Ethical Principles

A robust set of ethical principles—respect for persons, responsible stewardship, and justice and fairness—supports the adoption of norms to minimize the privacy risks that could befall individuals while enabling research and clinical care for public benefit to continue. Respect for persons requires one to give great “weight to autonomous persons’ considered opinions and choices while refraining from obstructing their actions unless they are clearly detrimental to others.”⁵⁶ Exercising autonomy includes self-determination, which requires that persons be allowed to make “important decisions about one’s life for oneself and according to one’s own values or conception of a good life.”⁵⁷ Respect for persons highlights an individual’s autonomy and recognizes that we should respect individuals’ ability to decide for themselves what they value, and how and when to act on those values. For example, an autonomous person should be able to decide whether to undergo a medical procedure based on personal considerations of risks, benefits, costs, and cultural and religious views. Forcing an individual to undergo a procedure, even for their medical benefit, would violate that person’s autonomy and would fail to demonstrate respect for the individual as a person. Respect for persons also encompasses respect for the individual’s dignity and privacy. Therefore, violation of an individual’s privacy, such as the misuse or unauthorized disclosure of whole genome sequencing data, demonstrates a violation of the principle of respect for persons.

Governments and societies that exercise responsible stewardship accept a duty to proceed prudently in promoting scientific advancement and emerging technologies. They recognize a shared duty to act in ways that demonstrate concern for all those who might be affected, and especially for those who are not in a position to represent themselves (e.g., children, the disenfranchised, vulnerable populations, and future generations). Rapidly advancing technologies such as whole genome sequencing present profound challenges for responsible stewardship because our understanding of the potential benefits and risks is largely incomplete and uncertain.⁵⁸ This makes it important that governments and societies take great care not to make decisions that have a substantial chance of causing irreversible harm to current or future generations, and especially those who have little or no say over such decisions. Responsible stewardship advises against decisions that are entirely precautionary (no action without complete certainty of security) or entirely proactionary (no limitations on science). Heeding the principle of responsible stewardship therefore neither thwarts the development of new scientific enterprises nor lets science advance unchecked on the fallible assumption that it is safe.

The principle of justice and fairness is, in important part, a commitment to ensuring that the unavoidable burdens of technological advances do not fall disproportionately on any individual or group, and that the benefits are widely distributed.⁵⁹ The principle of justice and fairness encompasses the idea of fair distribution in that it demands society ensure that risks not be disproportionately borne by any particular group and strive for “the broadest distribution of beneficial technologies.”⁶⁰ As such, the principle of justice and fairness entails protection for those who decide to share their whole genome sequence data to reduce the chances that they will be harmed by unauthorized disclosure or misuse.

These three principles, taken together, suggest that individuals are entitled to privacy protections that prevent undue and disproportionate burden. But these protections are not absolute. Prohibiting all gathering and sharing of whole genome sequence data would protect privacy absolutely, but still would fail to adequately respect persons. A total prohibition prevents individuals from choosing to participate in whole genome sequence research, even if they consider themselves adequately protected; it also fails to take into account individuals’

other interests, such as an interest in excellent medical care. Respect for persons demands respect both for individuals' privacy *and* for their interest in benefitting themselves and others from medical advances.

The Commission emphasizes that there is extremely good reason for individuals to choose to share information in a context where there is adequate protection for individual privacy: whole genome sequencing has the potential to be of substantial public benefit. The ability to share information is the sort of important decision that is central to autonomous action, which respect for persons commits us to recognize.

Respect for persons supports giving persons the opportunity to share their whole genome sequence information for scientific advancement, subject to strong baseline privacy protections. At the same time, individuals have a responsibility to safeguard their privacy as well as that of others, by giving thoughtful consideration to how sharing their whole genome sequencing data in a public forum might expose them to unwanted incursions upon their privacy and that of their immediate relatives. To be indifferent to the implications of disclosure of sensitive data and information about one's self is to act irresponsibly. That being said, it can be good and virtuous to share sensitive data about oneself in appropriate circumstances, for example, for the good of public health research or public education.

To determine what baseline privacy protections should be, we need to distinguish between access to, use of, and possession of whole genome sequence data. To *possess* whole genome sequence data is to have a copy of the data file and, therefore, to have access to it at any time. Having *access* to data implies the ability to manipulate and work with the data files. It is possible to access data that one does not possess; a researcher might be allowed to access data files in a secure database to address research questions without keeping a copy of the data. One can have access to data even if one does not (and either ethically or legally cannot) use it, as when whole genome sequence data are stored on a server available to download, but one does not download them. The *use* of data refers to seeking answers to questions by analyzing the data. A researcher could use data in a protected database without having either access to or possession of the data by submitting a query to the database manager and then receiving the results of the query from the database manager. In these ways, it is possible to allow researchers to work with whole genome sequencing data through access to or use of the data while maintaining the security of the data themselves and protecting the privacy of the individuals who contributed to the database. The confidentiality of information or data about persons can be maintained through a number of means designed to prevent unauthorized access to the data: these means are collectively called informational security or data security. Examples of data security mechanisms include legal limitations, locked drawers, and computer firewalls.

Presentations to this Commission indicated that whole genome sequence data could be used without actually possessing it: that is, technologies already are being developed to allow researchers to have limited computational access to select whole genome sequence data sets without physically transferring possession of all data files in the set.⁶¹ The researcher would be able to use the data for analysis, but would not maintain possession of the data. This means that possession of genomic information is neither necessary nor sufficient for its use. As with control of information, the use of information (including misuse and unauthorized use) in some cases will be of greater ethical salience than either access or possession.

Reconciling Competing Ethical Claims

The principles of public beneficence and intellectual freedom and responsibility support continued pursuit of whole genome sequencing to advance scientific understanding and medical progress. But these principles have components that suggest such pursuits should not be unrestrained. The positive argument for restraint is founded upon the principles of respect for persons, responsible stewardship, and justice and fairness, which together require implementing privacy protections and minimizing the chance of harm to individuals. But these principles do not suggest that privacy protections should erect absolute barriers to voluntary data sharing.

In moving forward with whole genome sequencing, respect for persons requires informing individuals about the foreseeable consequences of their decision to share their genomic data, including who has access to their whole genome sequence data and how these data might be used in the future. Respect for persons also counsels individuals who collect samples to determine patient and research participant preferences at the time samples are obtained so that they can choose whether to participate, or whether feasible limits on the use of their whole genome sequence data can be agreed upon. Providing individuals who are choosing whether to share whole genome sequence data with the information necessary to make a fully informed decision about the potential consequences—including who can access the data and how the data will be used—allows individuals to make an autonomous decision. The principle of respect for persons applies to all whole genome sequence data regardless of whether they were obtained in a research or a clinical context.

The Commission's principle of regulatory parsimony calls for "only as much oversight as is truly necessary to ensure justice, fairness, security, and safety while pursuing the public good."⁶² Regulatory oversight is appropriate in certain contexts—for example, disallowing certain types of research or permitting other types of research only when certain conditions are met. But some aspects of research—including data security protections for whole genome sequence data—remain outside most regulatory frameworks. For otherwise unregulated aspects of research, informed consent is one mechanism by which individuals can protect their own privacy. By informing individuals about the potential risks and benefits of participation in whole genome sequencing, along with information about the security protections in place, individuals can autonomously choose whether to provide a biological sample for use in whole genome sequencing research. In this way, informed consent is one means of reconciling the public good that can come from whole genome sequencing with the potential harms to individual privacy.

NEWBORN SCREENING

In the case of *Beleno v. Texas Department of State Health Services* parents sued, claiming that the Texas Department of State Health Services collected and stored newborn blood samples, subsequently making them available for research purposes, without seeking parental consent. The parents argued that the lack of proper consent was a violation of privacy. The out-of-court settlement that was reached resulted in the destruction of 4 million similar specimens that had been collected without parental consent.

Sources: *Beleno v. Lakey*, No. SA-09CA-188-FB (W.D. Tex. Sept. 17, 2009).; and Aaronson, B. (2010, December 8). Lawsuit alleges DSHS sold baby DNA samples. *The Texas Tribune*, TribBlog. Available at: <http://www.texastribune.org/texas-state-agencies/departamentof-state-health-services/lawsuitalleges-dshs-sold-baby-dna-samples/>.

The Commission is also mindful of democratic deliberation, an approach to collaborative decision-making that embraces respectful debate of opposing views and active participation by citizens. Democratic deliberation warrants engaging the public and fostering dialogue among the scientific community, policy makers, and those concerned with the issues raised by whole genome sequencing.⁶³ In this spirit, the Commission sought input from a broad range of voices, including members of the patient advocacy community calling for more participatory models of research and from researchers who feared further administrative burden.

The principle of democratic deliberation acknowledges that while decisions (e.g., recommendations, policies, and guidance documents) must be reached in a timely manner, those decisions need not—and generally should not—be unalterable, particularly when relevant new information emerges. Modern societies change rapidly, especially in the domain of science and technology, and decisions in changing realms are best considered provisional rather than permanent. Researchers and clinicians must be particularly mindful of the deliberative value of provisionality, of being tentative or temporary, as whole genome sequencing moves from the realm of research and enters the broader clinical context.⁶⁴ The transition is already raising new challenges, and the policies that were once created with the assumption that the research realm is clearly and cleanly separated from clinical contexts may no longer be either sustainable or desirable due to the reciprocal relationship that has developed between them. Clinical samples, stripped of identifiers and transferred to genomic databanks and biorepositories for broader use by researchers, contribute to the common good by making possible research that could not be done without large numbers of samples from which to generate data. Subsequently, medical benefits developed as a result of such research will be available to the broader population including the persons from whom the deidentified clinical samples were taken.

Conclusion

The Belmont principles and the principles articulated by this Commission suggest ethically important and practically useful guidelines for whole genome sequencing. Chief among these is that the principle of respect for persons requires strong baseline protections for privacy and security of data, while public beneficence requires facilitating ample opportunities for data sharing and access to data by clinicians, researchers, and other authorized users. Respect for persons further requires that any collection and sharing of an individual's data be based on a robust process of informed consent. The principle of responsible stewardship calls for oversight and management of whole genome sequence information by funders, managers, professional organizations, and others. The principle of intellectual freedom and responsibility provides further support for pursuing whole genome sequencing and seeking models for broad data sharing by promoting regulatory parsimony. Democratic deliberation is the foundation of the process that gave rise to this document, and others like it, and will continue to be the foundation moving forward. Democratic deliberation urges all parties to consider changes to policies and practices in light of the evolving science and its implications for enduring ethical values.

Finally, the principle of justice and fairness requires that we seek to channel the benefits of whole genome sequencing to all who may potentially benefit, and ensure that the risks are not disproportionately borne by any particularly vulnerable or marginalized group.

SECTION 2. POLICY AND GOVERNANCE

This section describes current policy and legal protections of genetic information and the ways in which genome sequence data are shared in the United States. There is no comprehensive federal law that protects genetic privacy. The Genetic Information Nondiscrimination Act (GINA) prohibits discrimination by employers and health insurers based on the results of genetic tests, but does not provide privacy protections. In addition, GINA does not address the complexity of large-scale genomic data. Many states have laws governing genetic information and some of these laws provide privacy protections, but the laws vary greatly from state to state. As a result, our laws lack the specificity required to encourage participation and secure public benefits from this emerging science, while still ensuring the protection of privacy.

To gain the most benefit from recent innovations in whole genome sequencing, researchers need as much data as possible, derived from broad public participation in whole genome sequencing research. Widespread participation will be achieved only if participants trust the research enterprise and are comfortable that their privacy interests are protected. Currently, the patchwork of state and federal laws does not provide uniform protection of genomic data privacy. Protecting privacy interests of individuals requires a spectrum of conditions to be in place, including ethical and trustworthy behavior by researchers and clinicians, sufficient security of information technology, and policies and laws that hold violators accountable.

Privacy Concerns about Genetic and Whole Genome Sequence Data

For as long as the nature of genetics and heritability has been understood, there have been concerns about misuse. During most of the 20th century, erroneous notions about genetics led to eugenic policies based on the idea that genetic “inferiority” should be eliminated. Since the launch of the Human Genome Project in 1990, scientific knowledge about genetic information has grown exponentially, especially in identifying genetic variations that cause disease. This new information has resulted in a heightened concern about privacy, and the implications of others knowing an individual’s genetic information.

To draw meaningful conclusions and answer broad research questions, researchers aggregate and share whole genome sequence data from large numbers of individuals. To garner widespread participation in research and maintain trust in the enterprise, users and holders of whole genome sequence data must guide themselves according to at least three facets of privacy and confidentiality. The first facet, the individual, requires fostering ethical behavioral norms for researchers and clinicians. Participants, patients, and consumers must be assured that those who have contact with identifiable data intend to use them in an ethical manner—namely, only for those uses for which the participant, patient, or consumer has given consent. Many individuals trust researchers and medical professionals to consider their needs along with the

greater good, despite substantial privacy concerns. A 2010 study of research participants' views on genomic research indicated that, while individuals expressed concerns about privacy and data security, they also understood the value of sharing whole genome sequence information. Overall, concerns about privacy did not outweigh their sense of the importance of sharing genomic data in the interest of a larger social good.⁶⁵

The second facet of privacy protection is information technology. Participants and patients must be assured that their data are secure. A 2006 survey queried the public's wariness about health information technology systems and found that 80 percent of survey participants were concerned about identity theft and fraud, 77 percent about health information being used for marketing purposes, and 55 percent about health information being misused by insurers or employers.⁶⁶ These concerns highlight the need for secure information technology systems tailored to sensitive biomedical information, including whole genome sequence data and information. These concerns build upon the need for fundamental trust in the ethical behavior of data users and in the security of the systems that store these data—participants and patients should be assured that they can rely on their consent to allow identified data to be used for certain purposes and not for others.

The third facet of privacy protection is policy. Policy-level protection requires that systems be in place to provide clear institution-level expectations of training and preparation to handle whole genome sequencing data and information, to ensure an atmosphere of trust and an expectation of security, and to provide recourse should individual and information technology privacy protections fail.

While rapid advancement of genomic science in the past decade has led to vast potential for valuable research and societal benefits through medical advances, privacy and confidentiality concerns persist. Without reliable protection from potential harms, perceived and real fears of privacy violation and discrimination could cause individuals to balk at sharing their whole genome sequence data, thus stifling scientific progress.

Current Sharing of Specimens and Whole Genome Sequence Data

The past few years have seen the rise of sharing whole genome sequence data through biorepositories (facilities that store large numbers of physical biospecimens containing genetic material and associated data and information that researchers can access) and databases. Biorepositories are categorized generally into four groups: disease-specific (e.g., cancer databases); longitudinal population studies (e.g., the United Kingdom biorepository); isolated populations (e.g., the Faroe Islands); or twin registries, used to distinguish between genetic and non-genetic bases for disease.⁶⁷ Biorepositories often have different missions and different governance structures and must reconcile the rights of individuals with potential societal benefit accordingly. Other organizations, such as academic institutions, government agencies, and private not-for-profit entities, store data in databases—repositories that do not contain physical biospecimens, but rather electronic versions of genome sequence files. For many purposes, it is no longer necessary to maintain actual stored DNA from an individual once the genome sequence data have been collected, because it is easier to share electronic data files than physical specimens.

Despite these differences, biorepositories and their associated databases share some commonalities. The collection of specimens and data and subsequent storage in biorepositories

and databases give rise to risks that might include minor harm to the donor in obtaining the biospecimen (such as bruising upon blood withdrawal); nonphysical harms such as discrimination, stigmatization, and untoward psychological impact upon discovering unwelcome information; group harms, like those incurred by the Havasupai; and ethical harms that arise when individuals are not treated with respect and dignity.⁶⁸ Various laws and regulations govern the ways that these data currently are collected, shared, and used in the United States and around the world.

U.S. Federal Agency Activity

In order to inform this report, the Commission sought information about human whole genome sequencing research sponsored by the 18 U.S. Common Rule agencies, and related privacy protections of the data generated in the research they sponsor (see Table 1). The Commission supplemented these responses with publicly available information.⁶⁹

Twelve of the responding agencies stated that they do not conduct research involving human genomics, have not advocated formally for policy changes, and do not anticipate policy changes related to genomics.⁷⁰

Table 1. Human genomics research in federal common rule agencies

Department/Agency	Conducts/ Sponsors Research Involving Human Genomics	Anticipates Proposing New Policies
Agency for International Development (USAID)	No	No
Central Intelligence Agency (CIA)	No	No
Consumer Product Safety Commission (CPSC)	No	No
Department of Agriculture (USDA)	No	Yes
Department of Commerce (DOC)	No	No
Department of Defense (DOD)	Yes	Yes
Department of Education (ED)	No	No
Department of Energy (DOE)	No	No
Department of Health and Human Services (HHS)	Yes	Yes
Department of Homeland Security (DHS)	Yes	No
Department of Housing and Urban Development (HUD)	No	No
Department of Justice (DOJ)	Yes	No
Department of Transportation (DOT)	Yes	No
Department of Veteran Affairs (VA)	Yes	As needed
Environmental Protection Agency (EPA)	No	No
National Aeronautics and Space Administration (NASA)	No	As needed
National Science Foundation (NSF)	No	No
Social Security Administration (SSA)	No	No

Six agencies—the Department of Homeland Security (DHS), the Department of Defense (DOD), the Department of Justice (DOJ), the Department of Health and Human Services (HHS), the Department of Veterans Affairs (VA), and the Department of Transportation (DOT)—currently sponsor genetic and/or genomic studies, and five maintain or support biorepositories and databases.⁷¹ The confidentiality, privacy, and security of samples and data stored by federal agencies are governed by a baseline of laws and regulations, including the

Health Information Technology for Economic and Clinical Health (HITECH) Act, the E-Government Act, the Federal Information Security Management Act, the Health Insurance Portability and Accountability Act (HIPAA), the Privacy Act, and the Policy for Privacy Act Implementation and Breach Notification.⁷² Several agencies have additional mission or function-specific policies that govern the entities they fund that perform whole genome sequencing studies.

DOD uses large-scale genomic data in the DNA Dog Tag program, a mandatory program that has collected and stored blood and tissue samples from every member of the Armed Forces since 1991. The program does not give service members the opportunity to opt out of this collection. DNA is extracted from the samples only if needed to assist in identifying human remains. Specimens stored in the repository are not used for any other purpose unless approved by the Assistant Secretary of Defense for Health Affairs. DOD has several policies for protecting and securing genetic information that address disclosure, medical records, and information systems.⁷³ DOD expects to increase the use of whole genome sequencing for forensic applications related to human remains identification.⁷⁴

Agencies within HHS routinely use or sponsor whole genome sequencing. The confidentiality and security of samples and data used by HHS are covered both by HHS-wide and agency-specific policies, laws, and regulations.⁷⁵ For example, one HHS agency, the Centers for Disease Control and Prevention coordinates efforts to conduct whole genome sequencing of residual dried blood spots archived by states after newborn screening with parental consent.⁷⁶ The Centers for Disease Control and Prevention also collects DNA specimens for its National Health and Nutrition Examination Survey, and the confidentiality of identifiable information collected is protected under the Public Health Service Act.⁷⁷ Another HHS agency, the National Institutes of Health (NIH), devotes resources to studying the influence of genetic factors on human health and illness. NIH has established a number of genetic data repositories, most notably the database of Genotypes and Phenotypes (dbGaP).⁷⁸ dbGaP stores various types of genetic information, including whole genome sequence data. Access to data stored in dbGaP is two-tiered: open access, which grants the public access to information about study design and aggregate phenotypic information; and controlled access, which grants researchers access to information including de-identified genotypes and phenotypes of individual study participants.⁷⁹ Researchers who seek controlled access must submit formal research requests that are reviewed and approved by NIH Data Access Committees.⁸⁰ NIH has implemented policies and procedures to which every researcher with access to dbGaP must adhere to protect the privacy and confidentiality of genetic and, specifically, whole genome sequence data.⁸¹

The Combined DNA Index System (CODIS) is a DNA database funded by the Federal Bureau of Investigation (FBI), a Department of Justice agency. CODIS consists of DNA profiles from the Convicted Offender Index, the Forensic Index, the Arrestee Index, the Missing or Unidentified Persons Index, and the Missing Persons Reference Index. The National DNA Index contains almost 11 million offender profiles.⁸² CODIS does not contain personally identifiable information, nor does it contain whole genome sequence data. To further protect the data in CODIS, access to computers containing CODIS software is limited to authorized users approved by the FBI. Unauthorized disclosure of DNA data in the National DNA database is subject to a criminal penalty.⁸³

DHS uses genetic data, but not whole genome sequence data, in several ways. DHS collects DNA from individuals who are arrested, facing charges, or convicted of federal or military

crimes. DHS also collects DNA from non-U.S. citizens who are detained under the authority of the United States. U.S. Citizen and Immigration Services can require genetic testing to establish familial relationships to determine immigration or refugee status. Finally, DHS is piloting a program for overseas refugees who request asylum for family members; refugees can be asked to voluntarily undergo familial relationship testing using a portable DNA testing device. DHS does not generally maintain or have access to the genetic information it collects from individuals; it sends DNA samples to the Department of Justice for processing and entry into CODIS.⁸⁴

VA has active research and clinical genomics programs. In 2012, VA launched the Million Veteran Program, which aims to collect one million biospecimens from veterans to explore the role of genes in health and disease.⁸⁵ VA treats genomic data as personally identifiable medical information protected under HIPA A, although it stores the biospecimens securely and without other traditional identifiers such as name. VA has applied for a Certificate of Confidentiality from NIH, and has several additional departmental policies to protect the privacy of identifiable medical information.⁸⁶ The Million Veteran Program database is accessible only to authorized researchers for projects that have been approved by appropriate VA oversight committees.⁸⁷

The Federal Aviation Administration, a Department of Transportation agency, is researching human factors related to aviation safety from a gene expression viewpoint (gene expression is the process by which genes are translated into proteins).⁸⁸ Specifically, the Federal Aviation Administration is researching how alcohol use, fatigue, and cosmic radiation change gene expression and is correlating changes in gene expression to human performance to improve aviation safety. The Federal Aviation Administration's intent is to have unique sets of molecular markers for these factors that are generally applicable across the broad human genetic spectrum with a high degree of specificity. Genetic data collected by the Department of Transportation are subject to a number of federal data security policies.

INTERNATIONAL BIOREPOSITORIES

While the United States has many publicly funded biorepositories of limited size, a number of countries have implemented or attempted to implement population-wide biorepositories.

In the United Kingdom, for example, a half million volunteers are being recruited to donate genetic material to be linked to medical records in a biobank. The biobank will obtain informed consent from its participants and will allow for withdrawal from the database. Participants can request: 1) complete withdrawal and destruction of existing samples, 2) discontinued participation but continued use of existing data, or 3) no further contact, but continued use of existing data.

Source: UK Biobank [website]. Retrieved from <http://www.ukbiobank.ac.uk/>.

Commercial Genetic Testing Companies

Over the past few years, accessibility and availability of commercial genetic testing and genotyping has greatly expanded. Companies like 23andMe, Navigenics, and Ancestry DNA provide an array of services including paternity testing, testing for predisposition to certain diseases and traits, genealogy and ancestry information, pharmacogenomics (the influence of genomic factors on drug response), and even private forensic tests to establish profiles of suspects not included in the federal CODIS database.⁸⁹ Most commercial genetic testing

companies currently do not conduct whole genome sequencing. Instead, they analyze hundreds of thousands of single-nucleotide polymorphisms (SNPs) or discrete variants throughout the genome, which they describe as “genotyping.”⁹⁰ Commercial genetic testing companies often conduct research that uses biospecimens submitted by their customers. Most recently, 23andMe patented one of their research discoveries, “polymorphisms associated with Parkinson’s disease.”⁹¹

Commercial entities face issues of data maintenance and storage similar to those of government-sponsored biorepositories and databases. They collect and analyze genetic and genotypic data and maintain electronic databases of consumer data. In addition, many commercial genetic testing companies have a research arm that conducts research on consumer data in biorepositories. Currently, there are no overarching federal or industry guidelines indicating how commercial genetic testing companies should operate, what privacy controls they should implement, or what limits they should put on the use of genetic data and information. Like government-sponsored biorepositories and databases, they can protect consumers by developing systems to promote ethical and trustworthy behavior of employees, strengthening the security of information technology systems, and developing company policies that hold violators accountable.

Privacy Regulations

Individuals who share their genomic information, like those who share any medical data, accept risks to their privacy and confidentiality should the data be improperly shared or used. Rather than a broad framework that provides general privacy protections, the United States has developed a patchwork of subject-specific regulations to protect the privacy of different types of information.⁹²

This system of subject-specific regulations includes, for example, regulations that protect census data, financial information, medical records, and video rental records, but does not include regulations that protect personally identifiable information that is not financial or medical, including name, address, occupation, affiliations, or internet activity.⁹³ As a matter of respect for persons as well as justice and fairness, a government can institute laws and regulations that help mitigate risks to individuals who share whole genome sequence data, and it can protect individuals from unwillingly or unwittingly sharing their whole genome sequence data. But it cannot eliminate all privacy risks while still effectively encouraging scientific, economic, and social progress. Just as the Commission strongly supports effective protections of privacy, it also emphasizes that sharing whole genome sequence data for the sake of medical research holds great potential for public benefit. The principle of public beneficence strongly encourages this sharing in a setting that provides adequate protections of privacy.

U.S. Privacy Regulations

The collection and protection of personally identifiable information is not new. The United States has collected personally identifiable information through the census and the tax systems since its early history. The government has recognized the importance of keeping this information secure and has implemented protections to ensure the privacy and security of these data.⁹⁴ Privacy laws and regulations permit but regulate cross-agency matching of collected data, and establish precedent that personal data shared by an individual for one specific purpose

should not be used to other ends, such as law enforcement or judicial proceedings, without their consent. In addition, traditional identifying information often is removed from the data files.⁹⁵

The United States has made several sectoral legislative attempts to regulate the privacy and security of personal data. These laws include the Fair Credit Reporting Act; the Privacy Act of 1974; the Confidentiality of Alcohol and Drug Abuse Act; the Family Educational Rights and Privacy Act of 1974; the Electronic Communications Privacy Act of 1986; the Video Privacy Act of 1988; the Children's Online Privacy Protection Act of 1998; and the Gramm-Leach-Bliley Act of 1999, also known as the Financial Services Modernization Act (requiring financial institutions to protect consumer privacy).⁹⁶

The laws cited above generally comport with "fair information practice" principles and practices first set forth in the Department of Health, Education, and Welfare (the precursor of HHS and the Department of Education) report, "Records, Computers and the Rights of Citizens."⁹⁷ The practices include the following principles: 1) there must be no personal data record-keeping systems whose very existence is secret; 2) individuals must be able to find out what personal information about them is in a record and how it is used; 3) individuals must be able to prevent information obtained for one purpose from being used for other purposes without consent; 4) individuals must be able to correct or amend a record of identifiable information; and 5) any organization creating, maintaining, using, or disseminating records of identifiable personal data must assure the reliability of the data for their intended use and must take reasonable precautions to prevent misuse of the data.⁹⁸

HIPAA, enacted in 1996, is the federal law most relevant to medical privacy.⁹⁹ Pursuant to the authority of Title II, HIPAA sets forth policies, procedures, and guidelines for maintaining the privacy and security of personally identifiable health information.

Figure 2. U.S. Federal Privacy Laws.

The HIPA A-mandated Privacy Rule was finalized in 2005. The Privacy Rule defines the circumstances in which an individual's protected health information—including any identifiable information—may be used or disclosed by a covered entity.¹⁰⁰ A covered entity is a health plan, a health care clearinghouse, or a health care provider that transmits any health information in electronic form.¹⁰¹ Under HIPA A, health information is not “identifiable” if there is “no reasonable basis to believe that the information can be used to identify an individual” or if it is stripped of the HIPAA identifiers.¹⁰² An individual's privacy rights under the Privacy Rule survive death.¹⁰³ While it is clear that genetic information is health information under HIPA A, HHS has stated that it is only covered by the Privacy Rule to the extent that it meets the definition of *protected* health information.¹⁰⁴ HHS has not clarified whether genetic or genomic information on its own is protected health information—that is, whether it falls under one of the HIPAA identifiers, such as “biometric identifier” or “any other unique identifying number, characteristic, or code.”¹⁰⁵

IDENTIFYING INFORMATION UNDER HIPAA

Names
 Address
 Dates
 Phone numbers
 Fax numbers
 Email addresses
 Social security numbers
 Medical record numbers
 Health plan beneficiary numbers
 Account numbers
 Certificate/license numbers
 Vehicle identifiers
 Device identifiers and serial numbers
 Web URLs
 Internet protocol (IP) addresses
 Biometric identifiers, including finger and voice prints
 Full face photographic images and any comparable images
 Any other unique identifying number, characteristic, or code (with certain exceptions)

A covered entity *must* disclose an individual's protected health information to him or her when specifically requested, and to HHS in the event of a compliance investigation or enforcement action.¹⁰⁶ A covered entity *may* disclose protected health information without consent in specifically enumerated circumstances, including for purposes related to treatment, payment, public health, and health care operations. A covered entity that discloses protected health information, however, must try to disclose only the minimum necessary to achieve its purpose.¹⁰⁷ There are no restrictions on the use or disclosure of de-identified health information, which is information that neither identifies nor provides a reasonable basis with which to identify an individual.¹⁰⁸

HITECH updated and revised HIPAA to extend slightly its privacy protections. HITECH adds business associates of covered entities to the list of those who can be subject to liability for disclosure of protected health information. It also strengthens the accounting requirements for the protection of health information, and imposes new notification requirements for covered entities to comply with when a breach has occurred.¹⁰⁹ The Office of the National Coordinator for Health Information Technology was created in 2004 through an Executive Order, and legislatively mandated in the HITECH Act. Its mission is to coordinate nationwide efforts to implement and use the most advanced health information technology and the electronic exchange of health information.¹¹⁰

While the requirements of HIPAA and HITECH apply only to “covered entities,” most academic institutions and federal agencies are required to follow the rules set forth for human research under the Common Rule. The Common Rule is a federal regulation governing human research in the United States that requires federally funded scientific research to be subjected to independent review by an institutional review board (IRB), have equitable subject selection, use procedures consistent with sound research design, minimize risks to participants, and obtain informed consent. Informed consent by participants must generally include, among other things, a description of the procedures in the research plan, an explanation of the risks and benefits to the participant, a description of the extent to which confidentiality of records will be maintained, and an explanation of the right to withdraw from the study.¹¹¹

Currently, whole genome sequence data obtained in the clinical context can be stripped of traditional identifiers and used for research purposes without IRB review or additional consent. This is because whole genome sequence data, when stripped of traditional identifiers (such as name or address), are not considered readily identifiable under the Common Rule.¹¹² The logic behind this is that while whole genome sequence data are unique to an individual, without a key that matches particular data to an identity, one could not readily ascertain *which* person the whole genome identifies. Similarly, while fingerprints are considered identifiable for law enforcement purposes, a fingerprint with no personal identifying information cannot point to whom that fingerprint belongs. In other words, a fingerprint does not have a name or address encoded directly in it. To discover the suspect’s identity, one must link the print to a database containing both traditional personal identifiers and fingerprints in order to know which person to arrest. Only research that uses data where the identity of the subject is, or may readily be, determined is considered human research under the Common Rule. Research using data stripped of traditional identifiers is not considered human research and therefore does not trigger Common Rule protections such as IRB review or consent.

Research using whole genome sequence data that have not been stripped of traditional identifiers (e.g., readily identifiable information) is considered human research. Accordingly, this research is governed by the Common Rule, meaning that IRB approval and informed consent must be obtained or waived by an IRB before the research can occur.

HHS recently published an Advanced Notice of Proposed Rulemaking (ANPRM), entitled *Human Subjects Research Protections: Enhancing Protections for Research Subjects and Reducing Burden, Delay, and Ambiguity for Investigators*, and collected comments on whether some types of genomic data should be considered identifiable. This ANPRM acknowledges that “there is an increasing belief that what constitutes ‘identifiable’ and ‘de-identified’ data is fluid” and that evolving technologies and the increasing accessibility of data could allow de-identified data to become re-identified.¹¹³ It also highlights the concern that “advances that have come in genetic and information technologies” might “make complete de-identification of

biospecimens impossible and re-identification of sensitive health data easier.”¹¹⁴ This is an ongoing discussion. A change to the Common Rule pertaining to identifiability could impact the collection and subsequent use of whole genome sequence data.

International Approaches to Regulating Genetic Information

The United States is not the only country deciding how best to prevent the misuse of genetic information. No international models yet exist regarding the misuse of and specific protections for whole genome sequence data. Some countries have enacted general privacy laws that encompass personal health information; patient rights’ acts that regulate, among other things, informed consent and confidentiality of medical information; and legislation that specifically regulates genetic information and genetic research. These laws differ from U.S. law, which is focused on prohibiting discrimination resulting from disclosure of genetic information rather than ensuring privacy of genetic information.

Many countries and foreign bodies have broad laws that regulate the use of personal information.¹¹⁵ Some of these, such as the European Union’s Data Protection Directive, offer special protection for more sensitive data, including personal health information.¹¹⁶ These privacy laws are far reaching—covering private and public institutions and many types of data—and are often overseen by data commissions or commissioners.¹¹⁷

In addition to these general data protection laws, many countries also have enacted patient rights’ laws that prohibit discrimination and require confidentiality of patients’ health information. These laws often require informed consent for disclosure of personal health information.¹¹⁸ Some of these laws, like those in the United States, also require that patients have access to their own medical records.¹¹⁹

In recent years, some countries have enacted laws specifically regulating genetic information and research. For example, Chile enacted a law in 2006 regulating genetic research that prohibits discrimination on the basis of genetic heritage and requires informed consent for research, confidentiality of genetic information, and anonymization of genetic data.¹²⁰ Some of these laws allow genetic testing only for individual health reasons or scientific research.¹²¹

Legal Protections of Genetic and Whole Genome Sequence Data

In light of mounting concerns about genetic privacy at the onset of the Human Genome Project, the U.S. Congress adopted legislation protecting against genetic discrimination. In 2008, Congress passed GINA, which aims to prevent genetic discrimination in the health insurance market (Title I) and in employment decisions such as hiring, firing, job assignments, and promotions (Title II).¹²² GINA does not protect against discrimination in the context of life insurance, disability insurance, or long-term care insurance. GINA’s protections apply to asymptomatic individuals, not those who have “manifested disease.”¹²³ Nor does it prescribe rules for genetic research.¹²⁴ GINA also expanded HIPA A privacy protections by applying prohibitions against genetic discrimination to all health insurers.¹²⁵

“There is certainly more room for legislation about privacy... the Genetic Information Nondiscrimination Act...is only a start. There are many more protections that the patient community would like that are not present in GINA.”

Greg Biggers, Council Member, Genetic Alliance; Chief Executive Officer, Genomera. (2012). Genomic Privacy, Data Access, and Health IT. Presentation to PCSBI, May 17, 2012. Retrieved from <http://bioethics.gov/cms/node/713>.

Under Title I of GINA, all health insurers are barred from: 1) using genetic information to determine coverage, eligibility, or premiums; 2) requesting or requiring genetic testing or genetic information for underwriting decisions; and 3) obtaining genetic information for underwriting purposes.¹²⁶ Additionally, insurers may not, on the basis of genetic information, impose a preexisting condition exclusion.¹²⁷ GINA extended HIPAA protections to cover persons purchasing individual, rather than group, health insurance policies.¹²⁸

GINA substantially expanded protections from genetic discrimination in employment. Under Title II of GINA, an employer with more than 15 employees cannot use an individual's genetic information when making employment decisions such as hiring, firing, job assignments, and promotions, nor can an employer request, require, or purchase genetic information about an individual employee or family member.

Although GINA prohibits specific types of misuse of genetic information by health insurers and employers, it does not address the use of or access to genetic data. In other words, GINA is an anti-discrimination law; it does not provide comprehensive privacy protections.

GINA provides a uniform federal law as a floor of protections against genetic discrimination, but also allows for state laws that provide additional safeguards.¹²⁹ Slightly fewer than half of all U.S. states have laws providing additional protection against discrimination in aspects of life, long-term care, or disability insurance not present in GINA.¹³⁰

About half of the U.S. states have policies governing genetic privacy. There is a great degree of variation, however, in what protections states afford their citizens regarding the collection and use of genetic data and, similar to the federal level, none have specific prohibitions for whole genome sequence data. Some states protect against the improper collection of genetic material without consent.¹³¹ Others protect against the improper disclosure of genetic information (and several of these states' laws do not specify to whom the disclosure is prohibited, whether to the donor or another party).¹³² Still others protect against improper retention of genetic information without consent.¹³³ The result of the variation in state laws is that there is no standard or comprehensive approach to the protection of genetic information in the United States, and the level of protection afforded to an individual's genetic information differs widely from state to state (for more information regarding the diversity of state law genetic protections, see Table 2 and Appendix IV: U.S. State Genetic Laws).

The U.S. Supreme Court has not established a constitutional right to informational privacy applicable to whole genome sequence data. Although the Supreme Court has addressed privacy rights of biomedical information in the context of the Fourth and Fourteenth Amendments, there is no case law addressing informational privacy in the context of whole genome sequencing.¹³⁴

Legal protections might be afforded if individuals have state property rights over their biospecimens, though courts have generally favored scientists over individuals from whom the specimen was taken.¹³⁵ The most famous case is *Moore v. Regents of the University of*

California in which the Supreme Court of California held that individuals are entitled to informed consent, but do not maintain property or privacy rights over cells after they have been removed from their body.¹³⁶

Table 2. Examples of State Genetic Privacy Laws

State	Protections
Arizona <i>AZ Rev. Stat. §12-2801-4, §20-448.02; 21</i>	Requires informed consent for genetic testing performed by health care providers, but does not address whether a non-health care provider may collect or analyze genetic material.
Oklahoma <i>Okl. St. § 1175</i>	Provides privacy protections for genetic information obtained from newborns, but does not provide similar protections for adult genetic data.
Hawaii <i>HRS §§ 431:10A-118</i>	Prohibits disclosure of genetic information by insurers, but does not specify the same for health care providers, nor does it protect against unwanted analysis of genetic material.
Missouri <i>§ 375.1309 R.S.Mo.</i>	Prohibits the disclosure of genetic information by persons who hold such information “in the course of business,” but does not address persons who have obtained it for any other reason.
Rhode Island <i>R.I. Gen. Laws §27-18-52, 52.3, §27-19-44, 44.1, §27-20-39. 39.1, §27-41-53, 53.1</i>	Prohibits the unauthorized disclosure of genetic information by insurance companies, but does not prohibit unauthorized disclosure by anyone else who may have access to genetic information.
Vermont <i>V.T. Stat. Ann. tit. 18, §9331 to 9335</i>	Prohibits people from performing genetic tests without consent and from disclosing the results of genetic tests without consent, but does not regulate the unauthorized obtaining or retention of genetic information.
Wyoming <i>Wyo. Stat. Ann. §14-2-701 to 710</i>	Prohibits the disclosure of genetic tests for paternity without consent, but does not address any other kinds of genetic tests.
Michigan <i>Mich. Comp. Laws §§ 333.17020, 333.17520</i>	Prohibits the performing of a genetic test by a health care provider without consent, but does not address performance of genetic tests by any other party, and does not prohibit unauthorized obtaining, retaining, or disclosure of genetic tests by any party.

State contract law also may provide legal protection if an individual has signed an informed consent document. In the context of genetic databases, researchers and participants can contractually determine who can access or use the data and on what terms, and the penalties for misusing protected information.

Conclusion

There is considerable concern in modern society about unauthorized or unintended disclosures of genetic information. While GINA prohibits genetic discrimination in the health insurance and employment contexts, it does not regulate use, access, security, or disclosure of genetic data, and does not specifically address whole genome sequence data or information. State-based privacy laws, consent forms, and IRBs collectively create a patchwork of privacy protections, but they neither comprehensively nor consistently protect the whole genome sequence data of individuals. In an era in which genomic data increasingly are stored and shared using biorepositories and genetic databases, there is little to no systematic oversight of these facilities.

To address the complex privacy and data security issues that arise in this arena, we need each of three robust facets of privacy and confidentiality protections of whole genome sequence data: individual researchers and clinicians; information technology systems; and laws, regulations, and institutional policies. Protection of personally identifiable data requires attention at all three broad facets of responsibilities. Individuals who collect, handle, store, and use data must recognize the ethical imperative of protecting the privacy of persons from whom they collect data. The information technology systems should be designed to protect persons by prohibiting the unauthorized access and release (intentional or unintentional) of identifiable data and protecting databases from intrusion. Laws and policies must protect persons from negative consequences of disclosure of information (e.g., discrimination) as well as enforce accountability and consequences for unauthorized access or disclosure.

It is clear that laws and regulations cannot do all of the work necessary to provide sufficient privacy protections for whole genome sequence data. Together with laws and regulations preventing misuse of data, individuals who receive such data have professional ethical obligations to protect the data that go beyond the limitations of the legal protections. Moreover, given how rapidly whole genome sequence technology is changing, it is in some ways preferable to adopt professional guidelines and policies rather than enact additional laws, since professional guidelines and policies are updated far more easily.¹³⁷ Guidelines and policies also might help those affected consider more deeply the privacy considerations at issue rather than focusing entirely on compliance with the letter of the law.¹³⁸

SECTION 3. ANALYSIS AND RECOMMENDATIONS

For this report on whole genome sequencing, the Commission has been mindful of the five ethical principles set out in its first report, as described in detail in Section 1. These principles for assessing emerging biotechnologies are public beneficence, responsible stewardship, intellectual freedom and responsibility, democratic deliberation, and justice and fairness. The Commission's principles complement and build upon the Belmont principles of respect for persons, beneficence, and justice. The Commission drew on both sets of principles to develop recommendations that facilitate responsible development of, access to, and use of whole genome sequencing.

The Commission focused on the principle of respect for persons by seeking to minimize risks to individuals willing to share their whole genome sequence data. Although individual benefits of whole genome sequencing are emerging, they are more elusive than predicted a decade ago. Many of the benefits anticipated from advances in whole genome sequence research will accrue to society generally through, for example, improved diagnosis and public health resulting from efficient medical treatment. Related privacy risks, however, primarily fall to individuals willing to share their genomic information. Risks might also fall to blood relatives of these individuals who carry similar genomic variants, thereby raising the stakes of privacy concerns in whole genome sequencing compared with most other types of research.

Strong privacy protections enable individuals to determine autonomously their preferred level of data and information sharing. When individuals have control and can govern sharing of their data at a level with which they are comfortable, they are more likely to have trust in the research or clinical enterprise, and are more likely to participate and share data, benefiting

society generally. These privacy interests are served by robust informed consent, data security provisions, and systematic oversight.

With the above in mind, the Commission identified the following areas for ethical analysis:

- Standards that allow individuals, if they wish, to access and share their whole genome sequence data and information;
- Security of whole genome sequence data and information and standards of access to and use of whole genome sequence databases;
- Informed consent to whole genome sequencing in the contexts of clinical care and research;
- Oversight of collection, storage, access, and use of whole genome sequence data and information; and
- Distribution of benefits from medical advances resulting from whole genome sequencing.

The recommendations presented in this section apply to individuals and entities that have an interest in, and work with, whole genome sequence data and information, both in the public and private sectors. Whole genome sequence data collected in the clinical setting are indistinguishable from whole genome sequence data collected in the course of research, and data increasingly move back and forth between the clinical and research settings. Ethical principles providing guidance in this area are based on a shared morality. While the implementation of recommendations that follow might be different depending on the entity involved in the collection, storage, access, and use of whole genome sequence data, the ethical issues at stake are the same.

The Commission's recommendations are also based on the fact that whole genome sequence data are inherently unique, meaning there is only one person in the world with that specific sequence. If the identity of the donor is not apparent to the user of the data, that individual is not readily identifiable. However, whole genome sequence data are often most useful when linked with information about physical characteristics, environmental factors, and medical records. These additional pieces of information, in turn, might make whole genome sequence data readily identifiable.

The Commission sees promise in the application of information technology to the field of whole genome sequencing. Information technology is able to tailor access to data with a degree of specificity not possible with traditional medical records, potentially making all types of whole genome sequence data more secure.

Uses of whole genome sequence data are rapidly evolving, and some of these uses do not fit easily into the current regulatory framework. The Commission, therefore, has crafted its recommendations to call attention to areas where it believes that current laws, regulations, and policies need to be reconsidered to honor applicable ethical principles and ensure that whole genome sequencing is most effectively used to the benefit of society and its individuals.

Strong Baseline Protections While Promoting Data Access and Sharing

Whole genome sequencing increasingly is being incorporated into clinical care and research. Presently, numerous national and state policies are in place to guard personally

identifiable health information and records of participation in research.¹³⁹ These policies should apply to all handlers of the data, from those who collect the data, to researchers, to third-party storage and analysis providers.¹⁴⁰ Privacy protection is an essential component of oversight of the use of whole genome sequencing in research and clinical care. Privacy protections should guard against unauthorized access to, and illegitimate uses of, data and information while allowing for authorized users of these data to advance public health.

For both ethical and practical purposes, it is important to carefully distinguish between access to, use of, and possession of whole genome sequence data. *Access* means being able to come in contact with the information, whether physically or electronically. It would be impossible to limit physical access to all sources of whole genome sequence data. We leave behind specimens containing our DNA in myriad public places—by discarding a coffee cup, for example—that could be used to perform whole genome sequencing. (It is more feasible of course to protect electronic access to whole genome sequence data in biorepositories and databases.) While individuals might have abandoned these genomic samples to public access, they nonetheless have a strong interest in whether the data they contain are collected and how they are used. On the other hand, sometimes persons might have authorized access to whole genome sequence data but misuse the information (e.g., by sharing information with a reporter). In certain cases, others simply have no right to know certain things about other people, no matter what they do with the information.¹⁴¹

Unauthorized access to data is not necessarily a problem in and of itself— despite having access to information, one can choose to not use it, and thereby not produce any harm. Misuse of information can therefore be more ethically significant than unauthorized access.

Laws and regulations can prohibit unauthorized parties from accessing or misusing whole genome sequence data, but it is impossible to guarantee that this will not occur. Laws and regulations can, however, provide deterrents to inappropriate access or misuse (such as fines), and compensation for the individuals whose data have been inappropriately accessed or misused.

Presentations to the Commission also indicated that authorized individuals can use data without having actual *possession* of those data.¹⁴² Technologies are being developed that allow “computational” access to data sets, which allow access and use without the user possessing the data set. In computational access, the data are possessed by a central party, but others can remotely perform analyses (i.e., use) of the data.

AN EXAMPLE OF COMPUTATIONAL ACCESS

Google, a major internet search engine, has collected data from its customers’ internet activity. Google views these data as a commercial asset and does not share possession of them. However, Google tools, such as Google Correlate and Google Trends, allow users to query Google’s collected data. A user can search for “stapler” to ascertain whether stapler and staple sales correlate, but users receive only the answer to their question (not access to the data mined by Google yielding the result). By using computational access, Google can give users access to answers, but not access to the data.

Source: Google. (n.d.). Google Trends. Retrieved from <http://www.google.com/trends/>.

Developments in the science of whole genome sequencing, which are progressing quickly, will require ongoing ethical consideration and democratic deliberation. Individuals and groups have differing sensibilities toward the privacy and publicity of whole genome sequence data, which might be relevant to distinguishing between acceptable and unacceptable uses of data. Perceived misuses of whole genome sequence data vary between cultures and individuals. For example, some individuals might be open to having a secondary researcher use his or her whole genome sequence data for an ancestry study. Members of the Havasupai tribe, on the other hand, strongly disapproved of their samples being used in ancestry studies, because these studies contradicted their traditional origin beliefs.¹⁴³ Some parents do not object to using Guthrie card newborn blood screening spots in future research without consent. Notable lawsuits in Minnesota and Texas, however, have indicated that some parents feel otherwise.¹⁴⁴ Requiring consent for future uses of readily identifiable whole genome sequence data, and encouraging consent for future uses of any data, are important to appropriate use. However, it is difficult to consent to all specific future uses in rapidly advancing scientific technology.

While privacy and confidentiality remain imperatives for protecting whole genome sequence data, it is also important to recognize that the American public, generally speaking, has become more open about communicating their health information. The development of online resources and communities reflects a shift in societal notions of what data should remain private (regardless of whether individuals would want to make it public). People now freely share information that was once considered inherently private or not suitable to be shared with a broad audience. The arrival of whole genome sequencing in health care has coincided with an era of greater openness about diseases that used to carry social stigma, such as HIV/AIDS, cancer, and mental health conditions. Many patients may choose to publicly share their stories, although others might not for privacy reasons.

Social attitudes about privacy are changing. There have been shifts not only in what information is considered private but also in how entities can realistically be expected to protect that privacy. Technological advances can trigger the creation of new privacy policies, such as the National Institutes of Health's (NIH) updated genome-wide association study policies.¹⁴⁵ While policy makers continue to focus on genetic non-discrimination policies that protect those whose privacy has been compromised, they have also begun to focus on data security policies that protect the data in the first place.¹⁴⁶ Finally, informed consent practices increasingly acknowledge that absolute privacy cannot be guaranteed.¹⁴⁷ Policies likely will evolve as notions of privacy continue to change. Future policies need to be flexible so that they can adapt to such advances in data security and information technology.

Recommendation 1.1.

Funders of whole genome sequencing research; managers of research, clinical, and commercial databases; and policy makers should maintain or establish clear policies defining acceptable access to and permissible uses of whole genome sequence data. These policies should promote opportunities for models of data sharing by individuals who want to share their whole genome sequence data with clinicians, researchers, or others.

Strong baseline privacy protections require a spectrum of policies starting with data handling through the protection of persons from future disadvantage and discrimination arising from misuse of their whole genome sequence data. It is critical, however, to ensure that privacy regulations allow individuals to share their own whole genome sequence data with clinicians, researchers, and others in ways that they choose.

Policy makers should also revisit efforts to strengthen protections against, and sanctions for, discrimination by treating the Genetic Information Nondiscrimination Act as a floor, not a ceiling, of protection. For example, because GINA does not cover symptomatic persons or address discrimination in life, disability, or long-term care insurance, persons with genetic diseases and predispositions are vulnerable to discrimination.¹⁴⁸

Advances in information technology should be pursued that promote appropriate use of whole genome sequence data while safe-guarding access to data files. For example, computational models that limit access to data files without preventing researchers' ability to analyze these data can be a valuable tool to protect privacy.

DATA PROTECTIONS THAT MOVE WITH THE DATA

The President's Council of Advisors on Science and Technology advocates a "tagged data element approach [that] allows for a sophisticated, fine-grained model of implementing strong privacy controls (including honoring patient-controlled privacy preferences where applicable) and strong security protection." This approach encourages privacy protections to move with the data across institutions, as opposed to changing protections based on the handler.

Source: President's Council of Advisors on Science and Technology. (2010, December). *Report to the President Realizing the Full Potential of Health Information Technology to Improve Health care for Americans: The Path Forward*, p. 52. Retrieved from <http://www.whitehouse.gov/sites/default/files/microsites/ostp/pcast-health-itreport.pdf>.

Last, policies regarding access to and use of data should take into consideration varying cultural, ethnic, and racial views about what might or might not constitute a misuse of data.¹⁴⁹

Currently, about half of the U.S. states have laws or regulations governing genetic privacy that outline illegitimate uses of these data. However, there is tremendous variation in these laws. In some instances, it is difficult to determine whether a state prohibits surreptitious testing of genetic material from an unwilling donor because of unclear language in the statutes. Some states prohibit unauthorized acquisition or analysis of genetic information, while others prohibit only unauthorized disclosure (and it is often unclear to whom disclosure is prohibited). Some laws at the state level encompass all genetic information, while others address only health-related information, or information obtained or used in particular settings (e.g., employment or insurance discrimination).¹⁵⁰ Therefore, whether genetic testing or whole genome sequencing without the consent of the donor is prohibited can depend on a combination of factors: who conducts the test, to whom the DNA belongs, what the test attempts to determine, how the results will be used, and in what state the testing takes place.¹⁵¹ Moreover, no states have laws or regulations specific to whole genome sequence data; some states have laws that include the words "DNA" and "genetic," although it is unclear whether these laws might be interpreted to cover whole genome sequence data and information.

Some of the topics specified in existing genetic laws could be used for whole genome sequencing laws as well. Types of regulations that would translate effectively into genomic protections include those regarding:

- Defining restrictions on what information can be stored in a biorepository, biobank, or genomic research database;

- Sharing of whole genome sequencing data, and if clinical data are shared with researchers, what type of information can be shared (e.g., stripped of traditional identifiers or not), and penalties for violations; and
- Using whole genome sequence information for life, disability, or long-term care insurance.

When individuals are asked about their concerns with respect to online health information, most focus on illegitimate uses of the data. They also cite discrimination, such as unauthorized use by insurers or employers, or use of their data for marketing purposes.¹⁵² However, the existing patchwork of state protections—with some states having no laws and the others having an inconsistent potpourri of legal prohibitions—does not protect all individuals from unauthorized uses. These uneven protections might also affect the development of trust in contexts where individuals are asked to share their whole genome sequence data for the public benefit in the course of research, clinical care, or commerce. Like all medical information, whole genome sequencing data should be ensured baseline privacy protections in all jurisdictions.

Recommendation 1.2.

The Commission urges federal and state governments to ensure a consistent floor of privacy protections covering whole genome sequence data regardless of how they were obtained. These policies should protect individual privacy by prohibiting unauthorized whole genome sequencing without the consent of the person from whom the sample came.

Currently federal and state laws protect data dependent on who collected them (i.e., a clinician, researcher, or consumer). Although a whole genome sequenced in the clinic is the same as a whole genome sequenced during research, data collected in the course of clinical care are governed by the Health Insurance Portability and Accountability Act, while data collected in the course of research are governed by the federal Common Rule for human research. The exact same data are treated differently depending on who collected the sample. Clinical data are collected to benefit the patient, while research data are collected to advance science and health care generally. However, the blurring of clinical and research lines, particularly in the field of whole genome sequencing, compels reconsideration of the differences between how clinical and research data are protected.

In addition, while the requirement for consent to whole genome sequencing is regulated in the clinical and research contexts (depending, to some extent, on whether or not traditional identifiers—such as name, address, or social security number—are attached to the sample), commercial genetic testing has opened a new loophole in privacy protections. One can now pick up a discarded coffee cup and send a saliva sample to a genetic testing company.¹⁵³ The potential consequences of unauthorized surreptitious testing could be profound (e.g., revealing disease risks to sway the disposition of a custody battle).¹⁵⁴ There are, of course, exceptions to this need for consent, such as use for legitimate law enforcement purposes. The Commission therefore recommends the prohibition of “unauthorized” whole genome sequencing—a term intended to carve out an exception for legitimate law enforcement.

Data protections should be tied to the *nature* of the data, not who collects them. Widely shared norms of justice and fairness dictate that similar kinds of data should be treated in similar ways, no matter in which state or health facility they are sequenced. If protections are inherent to the data, they should follow the data and dictate appropriate use. For example, meta-data

tags could be used to encode the level of security protections required for the data file and elements of consent (e.g., these data can/cannot be used in reproductive research). Using this approach, data will receive appropriately consistent use protections throughout their life span. More consistency in state protections of genetic and genomic data could also enhance privacy.

Treating like data alike is crucial to ensuring consistent protections for whole genome sequence information across the United States. Although states should enact genomic policies that are most relevant and important to their constituents, bringing such protections to a minimum standard that addresses privacy—while still allowing individuals to share their own data—would provide just and fair protections regardless of where one happens to reside.

Because the options for implementation of such protections are unclear, the Commission recommends that experts in federal law, state law, policy, and privacy be brought together to engage in further democratic deliberation regarding acceptable access to and permissible use of whole genome sequence data. The Commission will consider following up with stakeholders regarding: 1) suggested requirements to ensure a floor of protection of whole genome sequence data and data sharing in all states; and 2) the practical steps necessary to accomplish this goal, such as federal, state, or non-regulatory interventions.

Data Security and Access to Databases

Respect for persons requires honoring data privacy. Data privacy requires data security. Data security requires ethical responsibility and accountability from all those who handle whole genome sequence data and information. It must further be supported by policies and infrastructure to protect safe sharing of data.

Authorized users must have access to whole genome sequence databases to conduct research and make advances that will contribute to improved medical diagnostics and treatment for all. Security should allow only authorized individuals to access these data. However, breaches of unsecured protected health information have been publicized in the past, and can cause patients and research participants to doubt the security of their data. Unsecured health information can be accessed by unauthorized persons through means such as the loss or theft of unencrypted information on data storage devices, hacking of network servers, unauthorized disclosure, or improper disposal of paper records.¹⁵⁵ In a recent case, the unencrypted health information of over 800 patients was inadvertently embedded in PowerPoint presentations that were posted online.¹⁵⁶ In light of the possibility of data security breaches, it is important to address misuse of whole genome sequence data rather than wholly relying on preventing unauthorized access to these data.

“Technology can help save privacy, it can change your thinking, whether [it is] with respect to setting norms, [or] whether [it is] with respect to changing the way you set up the platform so that the platform can do more [computational] analysis... versus sharing the data around.”

Latanya Sweeney, Visiting Professor and Scholar, Computer Science Director, Data Privacy Lab, Harvard University. (2012). How Technology is Changing Views of Privacy. Presentation to PCSBI, August 1, 2012. Retrieved from <http://bioethics.gov/cms/node/748>.

When told of data hacking, some assume that the transition of private information to an electronic format makes it less safe. Quite the opposite might be true. In many respects, advances in information technology can be used to strengthen data security. For example, electronic files bear marks of who accessed them and when, allowing for more fine-tuned file tracking than is possible with paper records that may be surreptitiously accessed without a trace. In addition, current technology allows data files to be analyzed without the need to export the data files to other networks, that is, computational access can be allowed without data transfer. Even when individuals are willing to share their readily identifiable data and information for use in research, they might not want copies of their information saved on computers around the world. Access to and sharing of data files do not have to be one and the same. The Commission supports ongoing exploration and development of a set of best practice models that separate possession of, access to, and use of data.¹⁵⁷

Recommendation 2.1.

Funders of whole genome sequencing research; managers of research, clinical, and commercial databases; and policy makers should ensure the security of whole genome sequence data. All persons who work with whole genome sequence data, whether in clinical or research settings, public or private, must be: 1) guided by professional ethical standards related to the privacy and confidentiality of whole genome sequence data and not intentionally, recklessly, or negligently access or misuse these data; and 2) held accountable to state and federal laws and regulations that require specific remedial or penal measures in the case of lapses in whole genome sequence data security, such as breaches due to the loss of portable data storage devices or hacking.

Absolute privacy, many observe, is not possible in this as in many other realms. The greater potential for harm is not by virtue of authorized others *knowing* about one's whole genome make-up, but rather through the misuse of data that have been legally accessed.¹⁵⁸ For example, a clinician with a celebrity client would have legally authorized access to their client's whole genome sequence data for purposes of providing clinical care, but could not then sell that information to a tabloid. Researchers, clinicians, and others authorized to access whole genome sequence data should be guided by professional ethical standards so that they do not intentionally or inadvertently misuse these data.

In the event that data are mishandled or lost, those responsible should be aware of federal and state policies that require specific remedial actions, such as the requirement under the Health Information Technology for Economic and Clinical Health Act Breach Notification Rule to report breaches to the Department of Health and Human Services within the required number of days.¹⁵⁹ Those persons authorized to access whole genome sequence data should take part in regular training sessions to remain current on regulations governing whole genome sequence data privacy and security.

Public and private entities have different policies governing access to whole genome sequence databases by those seeking to use data for purposes other than that for which they were originally collected. Some policies create absolute prohibitions on releasing data to outside parties and associated penalties for violation, and some are more flexible, relying on the discretion of the person who holds the data.¹⁶⁰ Certificates of Confidentiality, for example, permit but do not require investigators to refuse access to research data by law enforcement officials and others.¹⁶¹ The use of Certificates of Confidentiality however, is limited; one study found that only 114 (0.04 percent) of 27,000 funded studies secured such a certificate.¹⁶²

Although empirical data on the use and effectiveness of these forms of privacy protection are not robust, scholars have questioned the strength of these protections, how well understood these protections are, and how they affect research participation.¹⁶³

Besides researchers, parties who might be interested in accessing information already compiled in whole genome sequence databases and biorepositories include law enforcement officials and marketing agencies. While commercial advertising can be a valuable tool in educating at-risk populations, this technique is often viewed as invasive when used as a way to sell products, for example, to selectively market a statin to someone with a genomic predisposition to high cholesterol.¹⁶⁴ In order to establish and maintain trust between members of the general public, clinicians, and the scientific research community, strong whole genome sequence data protections must be in place to secure data. Further, these limits on access must be communicated to those giving consent to have their whole genome sequenced in clinical, research, or consumer-initiated settings.

Obtaining a whole genome sequence data file by itself yields information about, but does not definitively identify, a specific individual. The individual still has “practical obscurity,” as his or her identity is not readily ascertainable from the data. Practical obscurity means that simply because information is accessible, does not mean it is easily available or interpretable, and that those who want to find specific information must expend a lot of effort to do so. While some experts might be able to determine an individual’s hair color or specific cancer risk from whole genome sequence data (a file of 6 billion As, Cs, Gs, and Ts), these data are not interpretable by the vast majority of individuals. In addition, even if we know that a whole genome sequence is from one individual, we cannot know which of the over 7 billion people on Earth that person is without a key linking the whole genome sequence information with a single person or their close relative. Therefore, while whole genome sequence data are uniquely identifiable, they are not currently readily identifiable.

Traditional identifiers have been stripped from samples or data in the clinical and research setting to mitigate the possibility of risks to the individual from whom the samples came. Removing traditional identifiers from samples and data can allow for research on samples previously collected for different purposes, deter users from illegitimately identifying individuals, and minimize the risk that users might recognize individuals and use this information subconsciously in their daily life.

Recommendation 2.2.

Funders of whole genome sequencing research; managers of research, clinical, and commercial databases; and policy makers must outline to donors or suppliers of specimens acceptable access to and permissible use of identifiable whole genome sequence data. Accessible whole genome sequence data should be stripped of traditional identifiers whenever possible to inhibit recognition or re-identification. Only in exceptional circumstances should entities such as law enforcement or defense and security have access to biospecimens or whole genome sequence data for non health-related purposes without consent.

The consent process should communicate limits on access and use to those having their whole genome sequenced in clinical care, research, and consumer-initiated contexts. These policies should apply to the original recipient of the data, as well as to all parties who work with the data, from those who collect the sample or data to third-party storage and analysis service providers.

An existing policy that could serve as a model is the Agency for Healthcare Research and Quality's confidentiality statute.¹⁶⁵ This statute was put in place to foster participation in research and provides a respected form of statutory protection for all identifiable data submitted to the Agency for Healthcare Research and Quality for research. The statute covers AHRQ, its grantees, and contractors. The statute also defines strict penalties for individuals who use these data for non-consented purposes.

Whole genome sequencing and related analyses generate enormous data sets. As of March 2012, the 1000 Genomes Project contained the sequence data of 1,700 people. The project database contained 200 terabytes of data, or the equivalent of 30,000 standard DVDs. This data set is a tremendous resource for biomedical researchers. At the same time, these data might not be useful to medical scientists and researchers without the computing power required to work with such a large data set. Exploring options for making these data available to qualified researchers is critical so that innovation and research are not slowed simply because researchers' computer networks cannot store these large data files.

"The explosion of biomedical data has already significantly advanced our understanding of health and disease. Now we want to find new and better ways to make the most of these data to speed discovery, innovation, and improvements in the nation's health and economy."

NIH Director Francis S. Collins, M.D., Ph.D., in a press release announcing the movement of the 1000 Genomes Project data set to the Amazon Web Services cloud. Retrieved from <http://www.nih.gov/news/health/mar2012/nhgri-29.htm>.

The question of how best to handle large data sets has gained attention throughout the government. The federal Office of Science and Technology Policy recently announced a "Big Data Research and Development Initiative," with the goal of "improving our ability to extract knowledge and insights from large and complex collections of digital data."¹⁶⁶ Six federal departments and agencies are part of the initiative. This initiative includes NIH, which recently made its 1000 Genomes Project public data set available on the Amazon Web Services cloud. NIH now expects that researchers can access and analyze the data at a fraction of the cost it would take to establish the computing capacity at their own institution.¹⁶⁷

Making whole genome sequence data accessible to researchers and clinicians is a promising step toward advancing medicine for the betterment of society. Moving data to third-party storage and analysis service providers, however, complicates the protection of individual data. When data are moved to third parties, an expanded range of data handlers and administrators have access to the data. Currently, a wide range of federal regulations govern the conduct of entities that handle protected health information.¹⁶⁸

Recommendation 2.3.

Relevant federal agencies should continue to invest in initiatives to ensure that third-party entrustment of whole genome sequence data, particularly when these data are interpreted to generate health-related information, complies with relevant regulatory schemes such as the Health Insurance Portability and Accountability Act and other data privacy and security requirements. Best practices for keeping data secure should be shared across the industry to create a solid foundation of knowledge upon which to maximize public trust.

Whole genome sequence data not stripped of traditional identifiers are considered “protected health information” and are covered under the HIPAA Privacy, Security, and Enforcement Rules and the Common Rule. The same regulations, policies, and ethical guidelines that protect such health information should also be in place to govern the sharing of whole genome sequence data with third-party storage and analysis service providers (those otherwise not considered covered health entities under HIPA A). Entities within the public and private sectors have developed a range of practices for protecting privacy. For example, the National Institute of Standards and Technology, the Office of the National Coordinator for Health Information Technology, and the Office for Human Research Protections are developing policies concerning access to and use of data by third parties. The National Institute of Standards and Technology recently released guidance on “Security and Privacy in Public Cloud Computing” and the Office of the National Coordinator for Health Information Technology worked to strengthen protections of identifiable health information handled by third parties.¹⁶⁹ Also, the Office for Human Research Protections issued guidance on research with coded private information or biological specimens.¹⁷⁰ Parties from the public and the private sectors should share their lessons learned to promote efficiency and avoid duplicating efforts. Because of the expansive potential of information technology, special attention should be paid to those practices that leverage information technology to protect privacy.

In order for the public to benefit as much as possible, best practices across the industry should be shared to ensure the privacy and security of whole genome sequence data and best gain the trust of those who have their whole genome sequenced in research, clinical, and consumer-initiated contexts. These best practices should include encrypting stored data and storing data without traditional identifiers when possible. Even when data are being accessed and used with informed consent, persons who access the data should be responsible and accountable for protecting the privacy of individuals and the confidentiality of the data. Respect for persons requires that these and other privacy protections do not become a competitive advantage for certain parties but rather serve, in both appearance and reality, as a reliable standard of individual protection.

Consent

Although not unique to whole genome sequencing, a well-developed, understandable, informed consent process is essential to ethical clinical care and research. Conveying the complexities of whole genome sequencing to an individual, however, is likely more difficult than for the average diagnostic test. To make the issue more complex still, informed consent documents are often overly legalistic and written at a reading level beyond the capacity of the average research participant.¹⁷¹ Studies have demonstrated varying levels of comprehension of consent documents, including reports of persons signing consent forms who are later either unable to recall whether they signed a consent form or describe to what they had consented.¹⁷²

To educate participants thoroughly about the potential risks associated with whole genome sequencing, the consent process must include in format ion about what whole genome sequencing is; how data will be analyzed, stored, and shared; the types of results the patient or participant can expect to receive, if relevant; and the likelihood that implications of some of these results might currently be unknown, but could be discovered in the future. As per usual consent protocol, permission to perform whole genome sequencing for a person who cannot

consent for him or herself should be obtained from an informed, legally authorized representative.

“How does consent change when a person lacks genetic health literacy, [or] when the health condition does not yet exist, but is a future probability, and some of those may be non-treatable conditions? When a health condition does not have implications for you, but it does for your offspring, what are the terms of consent there, especially if your offspring have different views about what they want to know about genetics, and then lastly, for these incidental findings versus disease specific testing..? I’ll just leave you with those questions, as the first of many that you will engage.”

Daniel Masys, Affiliate Professor, Biomedical and Health Informatics, University of Washington School of Medicine. (2012). Ethics and Practice of Whole Genome Sequencing in the Clinic. Presentation to PCSBI, February 2, 2012. Retrieved from <http://bioethics.gov/cms/node/658>.

Consent documents differ between research and clinical care. Research informed consent documents are often long and contain n elements such as a summary of the research, future uses of data, the option to opt out, potential risks of participation, conditions of compensation in case of injury, and potential benefits to the individual. Clinical consent documents contain some of the same elements but generally are shorter than, and not as detailed as, research consent forms. In fact, oral consent might be sufficient for low-risk clinical procedures. The reason clinical consent is less comprehensive is because clinical procedures are done for the direct benefit of the patient and thus pose less of a risk of conflicting interests. More substantive clinical written consent is required, however, for higher-risk procedures, such as those expected to produce pain, require anesthesia, or have a significant risk of complications.

In the research world, public opinion polls have found that individuals believe that being asked for consent throughout the course of research with their specimens or data would make them feel “respected and involved.”¹⁷³ Informed consent involves an autonomous decision to participate in research that results from a communication process between researchers and prospective research participants that describes the research and explains the risks and benefits associated with enrolling in the study. Respect for persons dictates that individual consent should be well-informed and honored, regardless of a person’s specific privacy preferences.

Clinical written consent documents for whole genome sequencing need not be as detailed as research consent documents, but these documents should still adequately explain whole genome sequencing and its potential impact upon privacy interests. A clinician should not frame whole genome sequencing as “just another type of blood test.” Consent procedures for clinical whole genome sequencing should build on those consent procedures already in place for discrete genetic tests. In the clinical context, as in research, individuals being asked to consent to whole genome sequencing should understand the volume of data and information to be generated, as well as the risks, benefits, and implications of the results of whole genome sequencing.

The Common Rule states that data and specimens collected in the clinic, when stripped of traditional identifiers, can be used in research without consent. Because consent requirements differ in clinical and research settings, researchers could theoretically seek out data and specimens collected in the clinic to bypass the more involved research consent requirements.

While it is acceptable to use clinical data and specimens in research, the Commission does not condone researchers circumventing Institutional Review Board approval by seeking out clinical data and specimens for use in research when they could not otherwise obtain IRB approval.

Whole genome sequencing involving minors raises additional ethical quandaries even when permission is properly obtained from an informed, legally authorized representative. First, federal privacy laws inconsistently define the age of consent—for the most part, the age of consent is 18 years old in the United States, yet in health care for certain contexts (e.g., mental health, contraception, or substance use), state laws allow consent by minors as young as age 14.¹⁷⁴ Second, the potential future risks raised by the current unknowns of whole genome sequencing are compounded in children who will see advancement in the science during their lifetime. While the function of all genes is not currently known, researchers will continue to determine the function of more genes, and could feel compelled to re-contact these children, as adults, with results that they are not prepared to receive or do not want. Third, whole genome sequence data obtained from a minor already could have been widely shared before the minor reached an age at which they could determine preferred data sharing limits themselves, thereby decreasing their autonomy. Whole genome sequencing in children, therefore, raises a number of unique issues with regard to fully informed decision making.¹⁷⁵

Some commentators are concerned that participants enrolled in research that requires especially large data sets, and who are given too much control over their data, will stifle the production of public benefits, such as improvements in clinical care, comparative effectiveness research, and epidemiological studies.¹⁷⁶ If individuals can choose not to participate in certain types of studies, the amount of data available to clinicians and researchers upon which to base their conclusions will be limited to some extent.

A range of consent frameworks are available that offer participants varying levels of control over their data. Most of these frameworks fall into four categories: 1) broad; 2) narrow; 3) tiered; and 4) participant-centric or dynamic approaches. Under broad consent, individuals are given the option to opt in or opt out of general, and often yet to be determined, future uses of their data. Narrow consent usually states that data will be used only by the research team carrying out a specific study or for a specific treatment in the clinic. Tiered consent processes allow individuals to specify acceptable and unacceptable uses of their sample and data at the outset of research.

“We also, as a research community, need to get used to the fact that there are patient-driven research objectives now and [patients] are coming together to do [research].”

Laura Lyman Rodriguez, Director, Office of Policy, Communications, and Education, National Human Genome Research Institute. (2012). Protection of Private and Public Genomic Databases. Presentation to PCSBI, August 1, 2012. Retrieved from <http://bioethics.gov/cms/node/749>.

Other consent models use computer-based participant-centered consent processes, which generally give participants freedom to determine their specific data sharing preferences up front, with some allowing participants to monitor and modify their preferences on an ongoing basis through a computer interface.¹⁷⁷ One prototype that has been implemented by a group called Consent to Research allows users to “attach” consent to the data they donate, and any researcher who can accommodate the provisions of that consent can use those data.¹⁷⁸ Alternatively, as databases become more technologically flexible, those donating biospecimens

can express preferences at the outset about permissible and impermissible uses that can be respected by future users of whole genome sequence data. Further, sample donors could electronically update their consent to encompass proposed new studies, with minimal hassle to the donor or the researcher. These models, however, can only be used by participants who have computer and internet access.

Some data have been collected on participant views of consent forms for biorepository research. Biorepository specimens and data files can be collected in clinical or research settings, and include (among other things) medical waste, newborn blood spot cards, and biopsy specimens. In one pair of studies, when asked about an opt out consent process, over 90 percent of participants agreed or strongly agreed that “DNA biobank research is fine as long as people can choose not to have their DNA included.”¹⁷⁹ Another study found that, despite privacy concerns, 60 percent of individuals surveyed would participate in a genetic biorepository, 48 percent of whom would prefer broad consent, while 42 percent would prefer project-specific consent with re-consent for each project.¹⁸⁰ These studies indicate that the majority of individuals enrolled in research are willing to share their data when asked, and the limited data available suggest that individuals vary widely across this spectrum of preferred form of consent.¹⁸¹ More research is needed, however, including on minority and marginalized populations where research participation is not as high.

The Common Rule, which governs most human research in the United States, requires that research consent be informed. Consent may be waived in some circumstances, and research with samples or data that are not readily identifiable is not considered human research (and thus does not fall under the Common Rule). Blanket authorization for all future uses of identifiable data, known and unknown, at the outset of a research study cannot legally satisfy the current requirements for informed research consent. However, the Common Rule Advanced Notice of Proposed Rulemaking (ANPRM) proposes a broad consent requirement that would give participants the opportunity to say “yes” or “no” to all future research uses of their data and specimens at the outset of research.¹⁸² The ANPRM also proposes that individuals could designate special categories of research in which they would not want their samples included, for example, reproductive research. By giving individuals the option to not participate in research to which they object, these individuals are respected as persons. Moreover, the option to not participate in a set of specific categories of research that one finds objectionable might actually encourage broader participation in research.

Broad consent at the outset of research might be a more practical solution than re-consent, or obtaining informed consent from every donor for a new use. Re-consent is difficult or, in some cases, impossible, as individuals frequently change residences, clinicians, phone numbers, and email addresses. Researchers also maintain that obtaining consent for each future study is burdensome and could hinder research.¹⁸³

Recommendation 3.1.

Researchers and clinicians should evaluate and adopt robust and workable consent processes that allow research participants, patients, and others to understand who has access to their whole genome sequences and other data generated in the course of research, clinical, or commercial sequencing, and to know how these data might be used in the future. Consent processes should ascertain participant or patient preferences at the time the samples are obtained.

Respect for persons requires obtaining fully informed consent at the outset of treatment or research. The informed consent process should cover the current proposed use of individuals' data, convey who might have access to their data, and explain potential future uses of these data, as well as what research results and incidental findings, if any, will be returned to the patients or participants.

Some patients might be surprised to discover that their whole genome sequence data obtained in the clinic could be used for research in the future without additional consent. With the blurring of the line between clinical care and research, data may be shared back and forth to improve clinical diagnosis and treatment.¹⁸⁴ Patients in the clinic should thus be explicitly informed that their whole genome sequence data could be used in research. When possible, individuals should be given the option to withhold their data from certain types of future research to avoid inadvertent complicity with research goals to which they are opposed. The Commission acknowledges the complexity of integrating individual options into the research enterprise, but if a framework is in place that accommodates identifying specific participant preferences at the time of enrolling in research, such as proposed in the ANPRM, these preferences should be honored.¹⁸⁵

As long as consent processes are equivalently effective in informing individuals about what they are consenting to, and as long as they do not unduly shape or undermine individuals' ability to make genuinely voluntary choices, there is no philosophical or ethical imperative to use one kind of consent process over another. In cases where the public stands to benefit from an activity and the research consent is fully informed and consistent with the ability to make autonomous choices, it might be advantageous to use consent processes that make it easier for individuals to participate—but most definitely not “trick” them into participating—at higher rates. In other words, the most important issue in consent is not the type, but rather that the consent is properly informed and consistent with voluntary choice.

Opt in consent policies assume that the default is not to go forward with some proposal, such as to consent to whole genome sequencing; the individual must actively consent to the proposal in order for anything to happen. Opt out consent means that, in the absence of a refusal, the default is participation, which tends to encourage higher rates of participation, a result particularly supportive of the public value of scientific and medical research that is otherwise ethically and legally sound.

BIOVU: AN OPT OUT DATABASE

Vanderbilt's BioVU database, which has collected DNA samples from almost 150,000 individuals, is an opt out database. Unless patients check a box indicating that they do not want their DNA in the BioVU database, their samples are included. In this way, BioVU is able economically to collect a large number of samples. To protect the data in its database, the samples are coded before being entered in the database. The computer system can match the DNA with information in medical records, but researchers working with the data do not know to whom the data belong. Data are stripped of identifiers before being shared with secondary researchers.

Vanderbilt University Medical Center. (2012). Vanderbilt BioVU. Retrieved from <http://www.vanderbilthealth.com/main/25443>.

Organ donation policies in Europe provide an example of opt out consent procedures. Austria, France, Hungary, Poland, and Portugal have opt out organ donation policies and all have organ donation consent rates above 99 percent.¹⁸⁶ The United States, on the other hand, uses an opt in system. Polls show that about 90 percent of Americans support organ donation, but only about 44 percent of people in the United States opt in to be organ donors.¹⁸⁷ This indicates that where Americans' values dispose them in favor of consent to organ donation, the often cumbersome and anxiety-inducing procedures of an opt in policy make them reconsider, passively resist, or fail to follow through with the extra steps (like filling out extra forms) required to opt in.¹⁸⁸

With some exceptions, federally funded research studies are required by law to obtain informed consent from all individuals enrolled in research or from their legally authorized representative.¹⁸⁹ The informed consent document is one component of the informed consent process. Current federal regulation requires that informed consent documents include, among other things, a description of the procedures in the research plan, an explanation of the risks and benefits to the participant, a description of the extent to which confidentiality of records will be maintained, and an explanation of the right to withdraw from the study.

By regulation, research participants can withdraw from research to which they consented at any time for any reason. However, complete destruction of whole genome sequence data is likely impossible. Although physical biospecimens and data files stored by the primary researchers can and will be destroyed at the time of withdrawal according to guidelines laid out in consent documents, the destruction of distributed copies of associated data files may not be feasible as distributed genome sequence data files can be stored on local computers or network servers. Therefore, those conducting whole genome sequencing research might not be able to promise complete withdrawal from a study.

Recommendation 3.2.

The federal Office for Human Research Protections or a designated central organizing federal agency should establish clear and consistent guidelines for informed consent forms for research conducted by those under the purview of the Common Rule that involves whole genome sequencing. Informed consent forms should: 1) briefly describe whole genome sequencing and analysis; 2) state how the data will be used in the present study, and state, to the extent feasible, how the data might be used in the future; 3) explain the extent to which the individual will have control over future data use; 4) define benefits, potential risks, and state that there might be unknown future risks; and 5) state what data and information, if any, might be returned to the individual.

Each government agency has its own enforcement authorities to protect research participants. For example, the Office for Human Research Protections has jurisdiction over human research conducted or supported by HHS, the Central Intelligence Agency has a Human Subject Research Panel, and the Department of Veterans Affairs uses a combination of Research Compliance Officers and its Office of Research Oversight. All these agencies should work together as each agency develops clear and consistent guidelines for their informed consent forms, enabling an individual to make a fully informed decision to participate in research.

Looking forward, clinical consent documents for whole genome sequencing will have to address a number of issues specific to whole genome sequencing: an explanation of the science, what types of results will be produced through whole genome sequencing, and whether whole

genome sequence data collected for clinical applications will be made available for research purposes.

Further, whole genome sequence data can provide information about many conditions, not just the condition under study. Acknowledging this, informed consent documents for studies involving whole genome sequencing should include which (if any) research results and incidental findings will be returned to individuals.¹⁹⁰

“Now, on the other side of the ledger...are the findings... which the patient is not expecting...which are going to have a dramatic impact of known consequence to them, and then the set of things for which there is much less certain impact.”

Richard Gibbs, Wofford Cain Professor, Department of Molecular and Human Genetics; Director, Human Genome Sequencing Center, Baylor College of Medicine. (2012). Ethics and Practice of Whole Genome Sequencing in the Clinic. Presentation to PCSBI, February 2, 2012. Retrieved from <http://bioethics.gov/cms/node/658>.

In whole genome sequencing, many individuals might want, and even expect, access to data or results.¹⁹¹ From the perspective of many individuals, the inability to receive or access their data denies them a fundamentally important sense of control over information about their own genomic makeup. While some individuals wish to share their data broadly for the advancement of science, others want control over their data to maintain their privacy, control information shared with intimate relations, or protect their right *not* to know results that might be discovered during whole genome sequencing. Individuals who seek return of data or results often feel that if someone else knows something unique about them, such as their risk for a particular disease, they ought to know it as well.¹⁹² On the other hand, some experts have said that although participant or patient preferences should be considered in the return of results, individual preferences are not a sufficient reason for agreeing to return results because of the importance of ensuring that the results are accurately communicated to individuals. These experts argue that the decision of whether to return incidental findings and other data should be in the hands of those who can more fully understand the broad implications of returning those findings, and what needs to accompany the return of raw results. They call for criteria to be developed, for example, by return of results committees.¹⁹³

There are, of course, reasons within our current research systems for not returning research results to individuals enrolled in research studies as well. First, by current law, only sequencing results from Clinical Laboratory Improvement Amendments (CLIA) compliant laboratories may be returned to individuals.¹⁹⁴ This requirement came about in the 1980s as a result of stories in the media that raised concerns about the quality of laboratory results, especially the return of false-negative Pap smear results.¹⁹⁵ This attention catalyzed the passage of CLIA in 1988, designed to improve quality and consistency in clinical laboratory testing. CLIA made it illegal to return to patients clinical results generated in a non-CLIA-certified laboratory.¹⁹⁶ Currently, most research is not conducted in CLIA-certified laboratories, including those laboratories performing whole genome sequencing.¹⁹⁷ In addition, researchers leading projects that are producing whole genome sequence data might not be qualified or trained to return sensitive, potentially devastating results directly to individuals, nor are grants usually structured to hire someone with the appropriate qualifications to do so.

Ethical analysis of whether and how individual research results and incidental findings should be returned is ongoing, and these questions are currently the subject of wide-ranging debate.¹⁹⁸ Many agree that participants should have the option to opt out of receiving research results and data from a study. There is less consensus on what should be done in cases where individuals want to receive incidental research results and data but, for example, researchers or clinicians did not themselves collect the information, are not trained in interpreting incidental results, did not perform the sequencing in a CLIA-approved lab, or have no prior knowledge of or relationship to the individual to appropriately convey the results. Alternatively, in some cases, investigators might feel personally obligated to provide research results that could be clinically meaningful.¹⁹⁹

One example that illustrates this dilemma is the Alzheimer's risk associated with certain variants of the ApoE gene. Individuals who carry the ApoE4 variant have a higher risk of developing Alzheimer's disease, but not everyone with this variant will develop Alzheimer's disease. Suppose that whole genome sequencing is being performed on a young adult for a breast cancer research study he or she is involved in, and the ApoE4 variant is discovered. Should this finding be returned? The finding is not clinically actionable—meaning that there is not an effective treatment or cure—and it is not certain that individuals with the ApoE4 variant will develop Alzheimer's disease. Some argue that the only acceptable reason to return an incidental finding is that the finding is clinically relevant and actionable, and the ApoE4 variant's association with Alzheimer's disease fails to cleanly meet these criteria.²⁰⁰

Others argue that it should be completely up to the individual whose whole genome is sequenced to make this decision.²⁰¹

A number of frameworks for return of research results and incidental findings have recently been proposed by broadly constituted groups. A recent consensus paper authored by academic researchers, legal scholars, and patient advocates determined that researchers should offer to return individual research results that 1) are analytically valid; 2) are in compliance with CLIA; 3) the patient has consented to receiving; 4) are clinically actionable; and 5) present an “established and substantial risk of a serious health condition.”²⁰² Another framework proposes grouping incidental findings into three “bins” including: “clinically actionable,” “clinically valid but not directly actionable,” (subdivided into low-, medium-, or high-risk incidental information groups), and “unknown or no clinical significance.”²⁰³ The bin into which the data fall in this model, in combination with other variants, determines if the result should be reported to the participant in a clinical context. Models also exist that are more finely tuned and consider multiple variables, such as participant preference (what results the participant does and does not want to know), significance of the result (analytic validity of the test and possibility for medical intervention), and communicability (literacy of the participant and clarity of the message).²⁰⁴

In contrast to these fine-tuned, multivariable return of results frameworks, many representatives of the patient advocacy community propose the wholesale return of whole genome sequence data to individuals. They argue that although universities or companies provide a service by performing whole genome sequencing, the individuals who supplied the samples should retain the right to control the use of the data, access to the data, and be able to share the data with whomever they choose (such as with researchers conducting other studies related to conditions affecting the individuals or the individuals' families).²⁰⁵

There is a difference however between the return of “data” and “information” in the context of whole genome sequencing. Some have suggested that regardless of whether meaningful

information (that is, analyzed data interpreted by experts) is made available, raw data might be valuable to individuals. Currently, the Food and Drug Administration is debating the classification of these data in the context of commercial genetic testing.

If companies are returning results with clinical or medical significance, commercial genetic services might be subject to regulatory requirements; but if they are simply returning unanalyzed whole genome sequence data files, regulatory requirements might not apply.²⁰⁶ For example, the commercial genetic test company Lumigenix does not interpret medically relevant genetic variants in-house. Rather, it provides customers with raw whole genome sequence data, inviting the consumer to use free genome analysis software to discover and interpret clinically relevant information on their own.²⁰⁷

This is a mere sampling of the many complex and detailed issues that need to be addressed before reaching a comprehensive set of actionable recommendations about whether and when incidental findings from whole genome sequencing can and should be returned to individuals with their fully informed consent.

Recommendation 3.3.

Researchers, clinicians, and commercial whole genome sequencing entities must make individuals aware that incidental findings are likely to be discovered in the course of whole genome sequencing. The consent process should convey whether these findings will be communicated, the scope of communicated findings, and to whom the findings will be communicated.

Recommendation 3.4.

Funders of whole genome sequencing research should support studies to evaluate proposed frameworks for offering return of incidental findings and other research results derived from whole genome sequencing. Funders should also support research to investigate the related preferences and expectations of the individuals contributing samples and data to genomic research and undergoing whole genome sequencing in clinical care, research, or commercial contexts.

Individuals undergoing whole genome sequencing in research, clinical, and commercial contexts must be provided with sufficient information in informed consent documents to understand what incidental findings are, and to know whether they will be notified of incidental findings discovered as a result of whole genome sequencing.²⁰⁸ Users of whole genome sequence data should continue supporting research into the management of incidental findings and individual research results obtained in both CLIA and nonCLIA-certified laboratories.

Previous research has generated many models and guidelines for returning incidental findings and other results obtained in clinical and basic research. In order to take the next step of translating these models into best practices for the return of results, additional data must be collected to inform the deliberations. In particular, research should be expanded to collect empirical data on participant, patient, researcher, and clinician opinions of each model, and the consequences and costs of implementing each model. These studies should examine the motivations of patients and participants enrolled in research, undergoing genome sequencing in the clinical context, or engaging in commercial whole genome sequencing to obtain their research results. Respect for patient and participant values is essential to guide the development of these tools ethically.

Facilitating Progress in Whole Genome Sequencing

Current protections for research participants emerged from a series of lapses in research ethics uncovered in the 1960s and 1970s in which clinicians and scientists conducted research without the fully informed consent or even knowledge of the research participants.²⁰⁹ One outcome of this history was the drawing of a bright line between clinical care and research. But this distinction is no longer so clear. Currently, large amounts of patient data are being collected in the health care setting, stripped of traditional identifiers, analyzed, and fed into research that might one day improve clinical care. This learning health system model both translates advances in health services research into clinical applications and collects data during clinical care to facilitate further advances in research.²¹⁰ With patient data increasingly being transitioned to electronic medical records, persons engaged in this type of research can also more easily access data to aggregate and analyze.²¹¹

Advocates of the learning health system model advocate encouraging intellectual freedom through clinical research and engaging in regulatory parsimony.²¹² Large amounts of data are essential for researchers to make correlations between genomic variants and disease states. Learning health system advocates and others call for standardized electronic health record systems and infrastructure to facilitate health information exchange so that data can be easily aggregated and studied.²¹³ Integrating whole genome sequence data into health records within the learning health system model can provide researchers with more data to perform genome-wide analyses, which in turn can advance clinical care. Several Institute of Medicine (IOM) working groups have supported these goals, outlining the desirability of establishing a universal health information technology system and learning environment that engages health care providers and patients. The IOM reports recommend that such a system include both genomic and clinical information, increased interoperability of medical records systems, and reduced barriers to data sharing.²¹⁴ The President's Council of Advisors on Science and Technology identified the lack of sharing electronic health records—with patients, with a patient's health care providers at other organizations, with public health agencies, and with researchers—as a barrier to improved health care.²¹⁵

Recommendation 4.1.

Funders of whole genome sequencing research, relevant clinical entities, and the commercial sector should facilitate explicit exchange of information between genomic researchers and clinicians, while maintaining robust data protection safeguards, so that whole genome sequence and health data can be shared to advance genomic medicine.

Performing all whole genome sequencing in CLIA-approved laboratories would remove one of the barriers to data sharing. It would help ensure that whole genome sequencing generates high-quality data that clinicians and researchers can use to draw clinically relevant conclusions. It would also ensure that individuals who obtain their whole genome sequence data could share them more confidently in patient-driven research initiatives, producing more meaningful data. That said, current sequencing technologies and those in development are diverse and evolving, and standardization is a substantial challenge. Ongoing efforts, such as those by the Standardization of Clinical Testing working group are critical to achieving standards for ensuring the reliability of whole genome sequencing results, and facilitating the exchange and use of these data.²¹⁶

In order for all persons to benefit from whole genome sequencing research, diverse populations must be involved in research. Consequently, it is incumbent upon the research community to earn and maintain the trust of individuals from a wide range of diverse populations across society. This trust is particularly important in minority and marginalized populations where levels of trust in the medical and research communities have been historically low.

To encourage such trust, some scholars and advocates have proposed alternative models for the interactions between researchers and individuals enrolled in research that attempt to increase transparency and shift the balance of control between these two parties.²¹⁷ As opposed to the traditional research model, in which there is usually little contact between the researcher and the individual enrolled in research beyond initial sample contribution, participant-centric initiatives put research participants at the center of the decision making, and are based on principles of respect and empowerment.²¹⁸ The federal government has shown an interest in giving patients a better understanding of disease, treatment, and care options through its establishment of the Patient-Centered Outcomes Research Institute.²¹⁹

The challenges we face today in whole genome sequencing are not (or only partially overlap with) the challenges we will face in the coming years as technologies continue to develop and mature. For example, one current concern is the integration of data into electronic medical records; in 20 years or less, society might have to decide if every newborn should have their whole genome sequenced and added to their electronic medical record. Due to rapid technological developments, today's policies must be crafted specifically enough to be actionable and targeted to address our current concerns, yet agile enough to ensure that we do not constrain our ability to adapt to evolving technology, research, and social norms related to privacy and sharing.²²⁰

Recommendation 4.2.

Policy makers should promote opportunities for the public to benefit from whole genome sequencing research. Further, policy makers and the research community should promote opportunities for the exploration of alternative models of the relationship between researchers and research participants, including participatory models that promote collaborative relationships.

Respect for persons implies not only respecting individual privacy, but also respecting research participants as autonomous persons who might choose to share their own data. Public beneficence is advanced by giving researchers access to plentiful data from which they can work to advance health care. Regulatory parsimony recommends only as much oversight as is truly necessary and effective in ensuring an adequate degree of privacy, justice and fairness, and security and safety while pursuing the public benefits of whole genome sequencing.

Therefore, existing privacy protections and those being contemplated should be parsimonious and not impose high barriers to data sharing.²²¹ While the Commission supports the intellectual freedom this access will encourage, clinicians and researchers must also act responsibly to earn public trust for the research enterprise.

Public Benefit

The federal government has made a substantial investment in genetics research, including whole genome sequencing, and the benefit of this investment has been realized in two major ways. First, disease diagnosis and treatment have been advanced, and the functions of many genes have been and will continue to be discovered, which will further improve clinical care in the coming years. Incorporating knowledge gained through advances in whole genome sequencing into the clinic could improve diagnosis and treatment of diseases that have brought turmoil and tragedy into the lives of individuals and their families. We have already begun to see some benefits resulting from these advances; for example, genetic variants that can lead to adverse drug reactions have been identified. In the future, as the genetic variations that underlie common diseases are discovered, clinicians will, in some instances, be able to detect predispositions to disease before those diseases occur, and begin treatment or recommend lifestyle changes before a patient exhibits symptoms. Second, an indirect economic benefit has been realized. The U.S. government invested \$3.8 billion in the Human Genome Project; it is estimated that this investment generated \$244 billion in personal income and \$796 billion in overall economic impact.²²² These health and economic gains not only benefit the public through improved health care but also through increased economic opportunities.

Thousands of citizens have participated in whole genome sequencing research personally, and all citizens help support government investment in whole genome sequencing through their participation in and support of our political system. Therefore, all citizens should have the opportunity to benefit from medical advances that result from whole genome sequencing.

Special caution should be taken on the part of researchers to ensure that their participants reflect as much as possible the rich diversity of our population. Different groups have genomic variants at different frequencies within their populations, and sufficiently diverse data must be collected so that advances arising from whole genome sequencing can be used for the benefit of all groups.²²³

Recommendation 5.1.

The Commission encourages the federal government to facilitate access to the numerous scientific advances generated through its investments in whole genome sequencing to the broadest group of persons possible to ensure that all persons who could benefit from these developments have the opportunity to do so.

Government investment in genomic research has resulted in public benefit through improved health care and in economic return on investment. The principle of justice and fairness requires that the benefits and risks of whole genome sequencing be distributed across society. Research funded with taxpayer contributions should benefit all members of society. To these ends, researchers should be vigilant about including individuals from all sectors of society in their studies, so that research findings can be translated widely into clinical care. The federal government should follow through on its investment in research and assure that the discoveries of whole genome sequencing are integrated with clinical care that can be accessed by all.

APPENDIX I: GLOSSARY OF KEY TERMS

Allele: a form of a gene at a particular location on a chromosome.

Biorepository: a stored collection of physical biological samples (e.g., blood or tissue) and associated data (e.g., medical information and policies). Sometimes called a biobank.

Carrier: an individual who has one normal and one mutated version of a gene.

Chromosome: X-shaped structure made of tightly wrapped DNA in the nucleus of the cell that carries genes from one generation to the next. Humans have 46 chromosomes (in 23 pairs).

Clinical utility: an assessment of the risks and benefits associated with a clinical test and the likelihood that the test will result in improved patient outcome.

Clinical validity: the degree to which a genetic test can predict clinical status, as measured by the strength of the association between the genotype and phenotype.

Copy number variations (CNVs): DNA mutations that occur when large sections of DNA are inserted or deleted during cell division.

Database: an organized collection of data or information (e.g., whole genome sequence data files and information).

Deoxyribonucleic acid (DNA): the molecule that contains the instructions to develop and direct the biological and chemical activities of a living organism.

DNA Sequencing: the process that identifies the order of the nucleotide bases in a strand of DNA.

Exome Sequencing: DNA sequencing of only the parts of the genome that make proteins (exons).

Exon: a stretch of DNA, part of a gene, that codes for a protein.

Gene: a piece of DNA that contains the information required for making a product that will have a biological function. A full set of genes is called a genome.

Gene-environment interaction: the environmental factors that can influence a gene's expression and the resulting phenotype.

Genetic test: a discrete test that examines a specific genetic location or a single gene, such as the test for Huntington's disease.

Genetic variation: differences in alleles of allele frequency between or among individuals or populations.

Genomics: the study of all the DNA (the genome) in an individual, and how parts of the genome interact with each other and the environment.

Genome: the full set of genes in an individual. Humans have about 20,000 to 25,000 genes in their genome.

Genome-wide association study (GWAS): compares large amounts of genetic data from individuals with and without a specific condition to identify DNA variants that correlate with diseases.

Genotype: the genetic make-up of an individual.

Genotype/phenotype correlation: the association between a certain mutation (genotype) and the resulting physical characteristic (phenotype).

Genotyping: analyzing discrete variants, from a handful to thousands, across the genome (i.e., more than a discrete genetic test, but less than whole genome sequencing).

Guthrie Card: piece of paper used to capture and store a few drops of blood collected from a newborn. DNA from the dried blood spot is then used to test for a range of genetic conditions and infections.

Heterozygous: when the genes or alleles on the two chromosomes are different.

Homozygous: when the genes or alleles on each of the two chromosomes are the same.

Incidental finding: a finding discovered in the course of clinical care or research concerning a participant that is beyond the aims of the clinical test or research but has potential health importance.

Individual research result: a finding discovered in the course of clinical care or research concerning a research participant that relates to the aims of the clinical test or research and has potential health importance.

Intron: part of a gene present between exons that does not directly code for a protein.

Locus: the location of a gene on a chromosome.

Mutation: a change in the DNA sequence. Mutations can arise from mistakes during cell division or from an outside source (e.g., radiation from the sun).

Nucleotide bases: the four chemical units that compose DNA. The bases are adenine (A), thymine (T), guanine (G), and cytosine (C). A always pairs with T on the opposite strand of DNA, and C always pairs with G. One A-T or G-C pair is called a base pair.

Phenotype: the expression of an individual's genotype. An individual's phenotype consists of their physical characteristics.

Public health utility: the likelihood that a clinical test will reduce disease burden and/or result in improved patient outcome in the population.

Single nucleotide polymorphisms (or SNPs): variations in the genome that involve single base pairs.

Structural variants: the insertion, deletion, duplication, translocation (the movement of DNA from one location to another on the same or another chromosome), or inversion (flipping over) of long DNA segments (greater than about 1,000 base pairs in length).

Whole genome sequence data: the file of As, Cs, Gs, and Ts produced as a result of whole genome sequencing.

Whole genome sequence information: facts derived from whole genome sequencing data, such as predisposition to disease.

Whole genome sequencing: determining the order of nucleotide bases— As, Cs, Gs, and Ts—in an organism's entire DNA sequence.

APPENDIX II: GENETIC AND GENOMIC BACKGROUND INFORMATION

Understanding Basic Genetic Architecture

Deoxyribonucleic acid (DNA) is the molecule that contains the instructions to develop and direct the biological and chemical activities of nearly all living organisms. DNA is a twisting pair of strands, called a double helix, made of four basic building blocks, or *nucleotide bases*. These bases are abbreviated A, T, C, and G. The As, Cs, Gs, and Ts are linked together in long strands. The A on one strand will link to a T on the other strand of the double helix, bringing

the two strands together at each point along the DNA strand, like rungs on a ladder. A always binds with T, and C always binds to G. One A-T or G-C pair is called a *nucleotide base pair*. If the DNA in a single human cell was stretched out, it would be about six feet long. If all the DNA in a human body was stretched out, it would reach almost 70 times from the earth to the sun and back.²²⁴ In order to fit this much DNA into cells, the long strands of DNA have to be stored compactly. In the cell, DNA is nearly always wrapped tightly into X-shaped structures called *chromosomes*, which prevent the long strands of DNA from tangling or being damaged. Chromosomes pass DNA from one generation to the next.

MENDELIAN GENETICS

Gregor Mendel, a 19th Century European monk, discovered the mechanism for trait inheritance in plants and animals. Mendel studied traits in peas, including flower color, stem length, seed shape, and seed color. Through selective pollination, he was able to observe how traits were expressed when two plants produced seed. He found that organisms have two copies of every inheritance “unit” (now called genes): one from each parent.

Chromosomes are located in the nucleus of a cell (a sub-compartment of the cell that stores DNA). Chromosomes are usually found in pairs, with one member of each pair coming from the individual’s genetic mother and the other from the genetic father (See Figure 3). Humans have 46 chromosomes, in 23 pairs. Of the 46 chromosomes, two are sex chromosomes (X and Y) that determine if an individual is male or female. In addition to the 22 pairs of chromosomes that all humans have, females inherit one X chromosome from each parent, making their 23rd pair XX, while a male inherits an X chromosome from his mother and a Y chromosome from his father, making his 23rd pair XY.

A complete set of DNA, or a full set of 46 chromosomes in a human, is called his or her *genome*. In humans, the genome is made up of approximately 3 billion nucleotide base pairs (A-T and G-C pairs). Nearly every cell in the human body contains a complete copy of the genome.

WHY IT IS GOOD TO HAVE TWO COPIES OF EACH CHROMOSOME

Having two copies of each gene ensures that if one gene on one chromosome of a pair is damaged, the gene on the other chromosome of the pair might not be damaged. In most cases, having only one functional copy of a gene is sufficient for normal function. This could be compared to having two kidneys: if one kidney is damaged, the healthy one can function well enough so that the individual can lead a relatively normal life.

Genes are specific regions of DNA on chromosomes. Genes are the basic physical unit of inheritance, and are passed from parents to their children. There are approximately 20,000-25,000 genes distributed over the 46 chromosomes. Together, these genes make up the blueprint for the body and how it functions. The location of a gene on a chromosome is called the *locus*, which is much like an address. For example, a gene can be found on chromosome 16 (e.g., the name of the street), on a particular end of the chromosome (e.g., the North or South end of a street), at a particular location (e.g., the house number).

Figure 3. The 23 pairs of human chromosomes.

Almost all genes come in pairs with one copy (or *allele*) from each parent. While the alleles might or might not be identical, the genes are the same (just like we all have ears, but our ears do not all look exactly alike). Every person has the same number of genes, although they might have different alleles from one another; that is, every person has the genes for cystic fibrosis (*CFTR*) and breast cancer (*BRCA1/2*), but most of us do not have disease-causing mutations in these genes.

In order to go from the blueprint in the genes to a functioning human, information in DNA is turned into proteins. Genes contain the instructions for making proteins that make up the human body. Examples of proteins include collagen, which is a major component of our hair and skin; and enzymes, a special type of protein, some of which break down the food we eat. If the DNA coding for a protein is mutated, it could result in that protein not functioning. For example, if the enzyme that breaks down lactose (a protein found in milk) is not assembled properly, it cannot break down lactose effectively and an individual is said to be lactose intolerant.

Not every single part of our DNA contains the instructions for making a protein, only certain parts of genes make proteins. These regions are called *exons*. The function of the regions of DNA that do not code for proteins, called *introns*, is unknown. Introns were once called “junk” DNA, but scientists are learning that introns are likely essential for the rest of the gene to function properly.

GENE-ENVIRONMENT INTERACTIONS

Cystic Fibrosis is a recessive genetic disorder, which means that a child must inherit a mutated copy of the *CFTR* gene from each parent to have the disease. While the genetic cause is clear, the severity of disease is linked to environmental factors such as exposure to second hand smoke, stress, and poor nutrition. Smoke in particular has been shown to interact with the *CFTR* gene and a secondary gene as well, worsening lung function in the patient.

Source: Collaco, J.M., et al. (2008). Interactions between secondhand smoke and genes that affect cystic fibrosis lung disease. *Journal of the American Medical Association*, 299(4), 417-424.

The term *genotype* refers to an individual's collection of genes or to the two alleles inherited for a particular gene. The expression of the genotype, through making proteins, contributes to the individual's outward characteristics, called their *phenotype*. The association between a certain mutation or mutations (genotype) and the resulting physical characteristics (phenotype) is called the *genotype/phenotype correlation*. This association is at the core of genetic testing and research.

Gene-environment interaction refers to how environmental factors modify the expression of a gene and, therefore, the trait, or phenotype. Some phenotypic traits are strongly influenced by genes, while others are more strongly influenced by the environment. Most traits are influenced by one or more genes interacting in complex ways with the environment.

Genetic Variation

A *mutation* is a change in a DNA sequence (see Figure 4). Mutations can come from mistakes that happen when DNA is copied during cell division, exposure to chemicals or harmful radiation (like UV rays from the sun), or infection with certain viruses. Some mutations occur in the cells of an individual's body and are not passed on to offspring, such as DNA damage in the skin caused by sunburn. Other mutations occur in the eggs and sperm and can be passed on to offspring, such as a mutation in the gene for sickle cell anemia.

The term *genetic variation* refers to differences in alleles and other genetic changes between or among individuals. Genetic variation can also refer to how often those differences in alleles occur between or among populations.

Humans have about 99.9 percent of our genetic information in common, but there is considerable genetic variation. The differences in our genomes can explain why we are diverse as individuals or populations in appearance, predisposition to specific diseases, and adaptation to our environment. Understanding genetic variation is at the heart of understanding the role of genetics in disease.

Genetic variations involving only a single nucleotide base (an A, C, G, or T building block) are referred to as *single nucleotide polymorphisms*, or *SNPs* (pronounced "snips"). Most people have thousands of SNPs in their genomes, but they often occur in the parts of DNA that do not make proteins, so they do not cause disease. When SNPs occur within a gene, they might cause disease by affecting the gene's function. Researchers have found SNPs that might help predict how an individual responds to certain drugs, their susceptibility to environmental factors such as toxins, and their risk of developing particular diseases. SNPs have been used extensively to study diseases that are passed from one generation to the next in families.

VNTR (variable number of tandem repeats)

THE SKY SKY SKY SKY SKY SKY IS BLUE

CNV (copy number variant)

THE SKY YYY IS BLUE

Figure 4. Types of Genetic Variations.

Genetic variation can also involve much longer stretches of DNA. *Structural variants* involve the insertion, deletion, duplication, translocation (the movement of DNA from one location to a not her on the same or another chromosome), or inversion (flipping over) of long DNA segments (greater than about 1,000 base pairs in length). One type of structural variation is a copy number variant. *Copy number variations* (CNVs) can occur when large sections of DNA are inserted or deleted during cell division. Scientists are trying to understand how copy number variation contributes to health and disease. Each person carries roughly 100 copy number variants, but many do not appear to have a disease linkage.

SICKLE CELL ANEMIA

Sickle cell anemia is caused by a SNP in the gene for hemoglobin, a protein in red blood cells that is responsible for carrying oxygen. If the hemoglobin gene is mutated on both alleles, an individual will have sickle cell disease, which leads to a shortened life span. If an individual has one normal hemoglobin allele and one mutated allele, however, they will not have sickle cell disease (because they also have one functional allele) *and* they will have some protection against malaria. Sickle cell disease is most common in populations who live in malaria-prone regions of the world, because carrying this mutation is actually protective against malaria.

Source: CDC. (n.d.). Protective Effect of Sickle Cell Trait Against Malaria Associated Mortality and Morbidity. Retrieved from http://www.cdc.gov/malaria/about/biology/sickle_cell.html.

How Genetic Variants Translate into Disease

Today, clinical genetic testing is used in individuals with a family history of disease; in other words, the tests are limited to those who are considered at risk of carrying known genetic variants that are linked to a particular disease. However, some clinical studies are evaluating the use of whole genome sequencing in regular clinical practice.²²⁵ In addition, individuals can try to bypass the traditional health care system and use the services of companies that offer consumers SNP analysis, whole exome sequencing, and more.

Very few genetic variants are directly linked to a specific disease, however some examples include cystic fibrosis, sickle cell anemia, and Huntington's disease. Targeted genetic tests have been developed for many of these diseases. Many other diseases are suspected to have a genetic component, but scientists have not determined which genetic variants might cause them. For example, heart disease could be caused by genetic mutations, but it is certainly not a simple case of one mutation in one gene. The genetic component of heart disease could be many mutations throughout the genome that interact with the environment to cause heart disease. Whole genome sequencing could reveal complex interactions between genes and disease, where a particular mutation on a certain gene, in conjunction with another mutation on another gene, or several other mutations on other genes, come together to cause disease.

Some of the genetic variants discovered during whole genome sequencing will have clear links to disease, but the majority will be unknown. Based on how they translate to disease, genetic variants can fall into six categories:

- *Variants of unknown significance*: An example of this might be when a piece of DNA has been cut out of one location on a chromosome and inserted into another location on the chromosome. The fact that the DNA is different is clear, but what that difference means, or how it will relate to disease, is unclear.
- *Nonmedical genetic markers*: These are genes that code for things such as eye color. If there were a mutation in one of these genes, it would not be something that would require medical treatment.
- *Carrier status*: An individual is a *carrier* of a variant if they have one normal and one mutated version of a gene. Most often, the individual is not affected by the disease, but they can pass the gene on to their children. An example is sickle cell disease, where individuals with one mutated version of the gene and one normal version of the gene do not have the full-blown disease themselves.
- *Susceptibility genes*: These are genes that make it more likely, but not certain, that an individual will develop a particular disease, i.e., they are "susceptible" to it. An individual might carry genes that make them susceptible to diabetes, but with proper diet and exercise, they will not necessarily develop diabetes.
- *Late onset genetic conditions*: Late onset conditions present later in life. Examples are Alzheimer's disease, Huntington's disease, and some degenerative eye diseases.
- *Medical conditions found by current prenatal genetic tests*: These are conditions that, if an individual has one or two copies of the gene, they will have the disease, and the disease will affect their health and quality of life throughout their life span. An example is phenylketonuria. Individuals with phenylketonuria cannot break down a particular amino acid and must follow a diet that is low in that amino acid.

Sequencing Strategies

DNA sequencing is the process of determining the exact order of the bases (nucleotides) in a strand of DNA. Since base pairing is predictable (A always pairs with T; G always pairs with C), knowing the sequence on one strand automatically reveals the sequence on the other strand. Sequencing technology has rapidly advanced in recent years, allowing scientists to make discoveries about the regulation, variability, and evolution of the human genome.²²⁶

A consequence of decreasing cost and increasing accessibility of sequencing technologies is the increasing use of whole genome sequencing. *Whole genome sequencing* is the process of sequencing all the DNA in an organism, in contrast to testing for only a handful of known mutations or sequencing a particular gene. Whole genome sequencing reads more than 95 percent of the genome, compared to SNP genotyping, which typically covers less than 0.1 percent of the genome. That said, knowing one person's complete DNA sequence does not necessarily provide useful clinical information, because each person's DNA is different from the DNA of others at millions of places. One goal of whole genome sequencing research is to create a reference catalog of all common and rare genetic variants in human populations so that the relationship between variants and disease can be studied. By comparing one person's whole genome sequence with other whole genome sequences, reference sequences, and associated health information, one can find places in the genome where, for example, a group of people with the same DNA mutation at the same locus all have the same disease. Comparisons like this will hopefully lead to meaningful associations and ultimately guide clinical and personal health decisions.

Exome sequencing might be an efficient alternative to whole genome sequencing in some cases. Exome sequencing selectively sequences only the part of the genome that make proteins (exons). An estimated 85 percent of disease-causing mutations are found in the exome.²²⁷ Therefore, sequencing only the exons, which make up about 1 percent of the genome, should be faster and less expensive than sequencing the entire genome, and is likely to identify most disease-causing mutations. Increasingly, exome sequencing is being used in clinical diagnostic testing. However, now that 80 percent of the genome has been found to have "biochemical function," with non-coding regions of the genome influencing the activity of genes that are spatially distant, exome sequencing that does not find an answer could be complemented by targeted sequencing of non-coding regions.

A *genome-wide association study (GWAS)* is a method that has been used heavily in recent years to identify links between specific genetic variations and specific diseases. The method involves studying the genomes of many people with and without a disease of interest and searching for genetic markers (e.g., SNPs) that can be used to predict the presence of a disease. GWASs alone cannot specify which genes cause disease; however, by looking at hundreds of thousands of SNPs, researchers can identify mutations that are more frequent in people with the disease than without. These mutations are therefore considered "associated" with the disease. Disease-associated SNPs are used as markers or pointers to the region of the genome where a disease-causing mutation is likely to be found.

The Challenges of Analyzing Whole Genome Sequence Data and Identifying Disease Associations

The primary goal of whole genome sequencing research is to describe the relationship between genotype (genetic variants) and phenotype (physical characteristics, including

disease). Whole genome sequence data alone will not provide a complete understanding of disease. The data must be linked to phenotypic data, such as medical records. Environmental data will also be needed to fully understand gene-environment interactions.

A challenge of whole genome sequencing research is the hard-to-detect relationship between genetic variant and phenotypic trait, such as disease risk. To interpret an individual's disease risk, one must have reliable information about every validated genetic disease to use as a standard of comparison. Currently, there is no central, publicly available repository of all variants found to be associated with a clinically relevant trait or disease.

Refinements must also be made to take into account the genomic diversity of the human population. While no "private" variants have been found only in one population and not in others, many variants occur at different frequencies in different populations (for example, a particular SNP might be common in one population and rare in another). Studying genetic variation across populations can provide some, but not all, clues to the causes of health disparities.²²⁸

Finally, even if a specific mutation is linked to a disease, the expression of that gene and environmental interactions can result in different phenotypic effects in different people. In other words, one person carrying a particular mutation might develop the disease and another person with the same mutation might not, or that person might exhibit the disease in a more or less severe form. Further, a single mutation in one gene rarely leads to the particular phenotype of an individual.

The current clinical value of whole genome sequencing for linking genomic variants to disease remains challenging because of the many gene-gene and gene-environment interactions. Thus, the field continues to work toward establishing the *clinical validity* (future disease positive and negative predictive value stratified by exposure), *clinical utility* (targeted interventions to reduce disease risk among persons with the profile) and *public health utility* (comparing reduction of disease burden in the population based on genomic analysis) of whole genome sequence data.

APPENDIX III: GUEST PRESENTERS TO THE COMMISSION REGARDING PRIVACY AND WHOLE GENOME SEQUENCING

George Annas, J.D., M.P.H.

Chair, Health Law, Bioethics & Human Rights; William Fairfield Warren Distinguished Professor, Boston University School of Public Health

Richard Gibbs, Ph.D.

Wofford Cain Professor, Department of Molecular and Human Genetics; Director, Human Genome Sequencing Center, Baylor College of Medicine

Retta Beery

Mother of twins who benefitted from diagnosis made possible by whole genome sequencing

Jane Kaye, D.Phil., L.L.B.

Director, Centre for Law, Health and Emerging Technologies (HeLEX), Oxford University

Greg Biggers

Council Member, Genetic Alliance; Chief Executive Officer, Genomera

Ken Chahine, Ph.D., J.D.

Senior Vice President and General Manager, Ancestry DNA, LLC

Ellen Wright Clayton, J.D., M.D.

Craig-Weaver Professor of Pediatrics; Professor of Law and Director, Center for Biomedical Ethics and Society, Vanderbilt University

Leonard D'Avolio, Ph.D.

Associate Center Director for Biomedical Informatics, Massachusetts Veterans Epidemiology Research and Information Center (MAVERIC), Department of Veterans Affairs; Instructor, Harvard Medical School

James P. Evans, M.D., Ph.D.

Clinical Professor and Bryson Distinguished Professor of Genetics and Medicine, Department of Genetics, University of North Carolina School of Medicine

Madison Powers, J.D., D.Phil.

Professor, Department of Philosophy; Senior Research Scholar, Kennedy Institute of Ethics, Georgetown University

Laura Lyman Rodriguez, Ph.D.

Director, Office of Policy, Communications, and Education, National Human Genome Research Institute, National Institutes of Health

Mark A. Rothstein, J.D.

Herbert F. Boehl Chair of Law and Medicine, University of Louisville School of Medicine

Bartha Knoppers, Ph.D.

Director, Centre of Genomics and Policy; Canada Research Chair in Law and Medicine, McGill University

Daniel Masys, M.D.

Affiliate Professor, Biomedical and Health Informatics, University of Washington School of Medicine

Amy McGuire, J.D., Ph.D.

Associate Professor of Medicine and Medical Ethics; Associate Director of Research, Center for Medical Ethics and Health Policy, Baylor College of Medicine

Melissa Mourges, J.D.

Assistant District Attorney; Chief, Forensic Sciences/Cold Case Unit, New York County District Attorney's Office

Pilar Ossorio, Ph.D., J.D.

Associate Professor of Law and Bioethics, University of Wisconsin-Madison

Erik Parens, Ph.D.

Senior Research Scholar, The Hastings Center

Latanya Sweeney, Ph.D.

Visiting Professor and Scholar, Computer Science; Director, Data Privacy Lab, Harvard University

John Wilbanks

Founder, Consent to Research; Senior Fellow, Kauffman Foundation; Research Fellow, Lybba

Susan Wolf, J.D.

McKnight Presidential Professor of Law, Medicine & Public Policy; Faegre & Benson Professor of Law; Professor of Medicine; Faculty Member, Center for Bioethics, University of Minnesota

Professor of Law, George Washington
University

The map displays the following distribution of laws across the United States:

- Comprehensive Law (Dark Green):** CA, NV, OR, WA, NM, SD, IL, NY, VT, NH, ME, FL.
- Limited Law (Medium Green):** MT, ND, MN, WI, MI, IN, OH, PA, WV, VA, NC, SC, GA, AL, MS, AR, MO, IA, NE, WY, UT, AZ, CO, KS, OK, TX, LA, KY, TN, MS, AL, GA, FL.
- No Law on Point (Light Green):** ID, MT, ND, MN, WI, MI, IN, OH, PA, WV, VA, NC, SC, GA, AL, MS, AR, MO, IA, NE, WY, UT, AZ, CO, KS, OK, TX, LA, KY, TN, MS, AL, GA, FL.

An inset map shows Alaska (AK) and Hawaii (HI) in the dark green category.

* Map and table current as of March 2012.

State	Citation	Consent required to PERFORM genetic tests	Consent required to OBTAIN genetic information	Consent required to RETAIN genetic information	Consent required to DISCLOSE genetic information	Application/ context limited to
AL						no law on point
AK	Alaska Stat. §§ 18.13.010 through 18.13.100 (2011)	X	X	X	X	comprehensive law
AZ	Ariz. Rev. Stat. §§ 1-602, 12-2801 through 12-2804, & 20-448-02 (2011)	X			X	ordinary course of business
AR	Ark. Code. Ann. §§ 1643-1101, 20- 35-101 through 20-35-103 (2010)	X			X	ordinary course of business
CA	Cal. Civ. Code §§ 56.17, 56.265 (West 2010); Cal Ins Code 10123.35, 10148 through 10149.1 (2010)	X	X		X	ordinary course of business/ insurance
CO	Colo. Rev. Stat. §§ 10-3-1104.6 & 10- 3-1104.7 (2010)	X	X	X	X	healthcare provider or insurance company
CT						no law on point
DC						no law on point
DE	16 Del. Code Ann. §§ 1201 through 1208	X	X	X	X	comprehensive law
FL	Fla. Stat. § 760.40 (2010)	X			X	comprehensive law
GA	G.A. Code Ann. §§ 3354-1 through 33-54-8 (2011)	X	X		X	insurance
HI	Haw. Rev. Stat. §§ 431:10A-118 (2010)				X	insurance
ID						no law on point
IL	§ 225 Ill. Comp. Stat. 135/90, § 410 ILCS 513/1 through 513/91 (2011)				X	comprehensive law

WY	Wyo. Stat. Ann. §14-2701 to 710	X			X	perform: comprehensive prohibition; disclose: paternity law

End Notes

- ¹ The individuals mentioned in these vignettes have given their permission to have their names included.
- ² For more detail, please see Section 2: Policy and Governance-Privacy Regulations.
- ³ The Genomics and Personalized Medicine Act of 2006 (S. 3822, 109th Cong. [2006]; subsequently reintroduced in the Senate in 2007 and in the House of Representatives in 2008 and 2010) encouraged accelerating genetics and genomics research and translating knowledge gained into clinical and public health applications. The proposed bill stated that “pharmaco-genetics has the potential to dramatically increase the efficacy and safety of drugs and reduce health care costs, and is fundamental to the practice of genome-based personalized medicine.” The Act identified several drugs that are more or less effective in people with particular genetic profiles, including the cancer drug Gleevac, the breast cancer drug Herceptin, and the acute lymphoblastic leukemia drug 6-mercaptopurine. All four bills were referred to committee and were not enacted.

²⁹ The Commission reached out to the heads of the 18 federal agencies and departments that have adopted the federal Common Rule for protecting human research participants. They are: Department of Agriculture; Department of Commerce; Department of Defense; Department of Education; Department of Energy; Department of Health and Human Services; Department of Homeland Security; Department of Housing and Urban Development; Department of Justice; Department of Transportation; Department of Veterans Affairs; Agency for International Development; Consumer Product Safety Commission; Environmental Protection Agency; National Aeronautics and Space Administration; National Science Foundation; Social Security Administration; and the Central Intelligence Agency.

³⁰ Request for Comments on Issues of Privacy and Access With Regard to Human Genome Sequence Data, 77 *Fed. Reg.* 18, 247 (March 27, 2012).

³¹ For example, the American College of Medical Genetics and Genomics is taking the lead in considering which results ought to be returned. A number of federal agencies have looked into direct-to-consumer testing, including the Secretary's Advisory Committee on Genetic Testing in its report "Enhancing the Oversight of Genetic Tests: Recommendations of the SACGT" (http://oba.od.nih.gov/oba/sacgt/reports/oversight_report.pdf); its successor, the Secretary's Advisory Committee on Genetics, Health, and Society in its report "U.S. System of Oversight of Genetic Testing: A Response to the Charge of the Secretary of Health and Human Services" (http://oba.od.nih.gov/oba/sacghs/reports/sacghs_oversight_report.pdf); and by the Government Accountability Office first in its 2006 report "Nutrigenetic Testing: Tests Purchased from Four Web Sites Mislead Consumers" (<http://www.gao.gov/new.items/d06977t.pdf>) and in its 2010 report "Misleading Test Results Are Further Complicated by Deceptive Marketing and Other Questionable Practices" (<http://www.gao.gov/products/GAO-10-847T>). The Food and Drug Administration has also considered the issue of direct-to-consumer testing, but has not yet published any formal recommendations. And the American Heart Association recently published a report entitled "Genetics and cardiovascular disease: a policy statement from the American Heart Association" that discussed gene patenting and insurance coverage of genetic tests (Ashley, E.A. et al. (2012). Genetics and cardiovascular disease: A policy statement from the American Heart Association. *Circulation*, 126).

³³ National Commission, op cit.

³⁴ PCSBI, (2010, December), op cit.

³⁵ Ibid, pp. 24-25, 113.

³⁶ The distribution of both scientific knowledge and subsequently of economic opportunity in the field of genome sequencing has been debated within the legal system. In a recent example, Myriad Genetics attempted to patent the *BRCA1* and *BRCA2* genes, which are associated with breast and ovarian cancer. Myriad Genetics' actions were contested by the American Civil Liberties Union, which argued that they were in violation of the First Amendment. In August 2012, a U.S. federal appeals court ruled that the company has the right to patent the two genes, stating that the patents would encourage innovation, but simultaneously denied the company's attempt to patent methods comparing or analyzing DNA sequences. Reuters. (2012, August 16). Court reaffirms right of myriad genetics to patent genes. *New York Times*. - ⁶⁸ In the early 1990s, researchers obtained consent from the Havasupai Indian tribe to collect samples and conduct research on a genetic link to diabetes. The University of Arizona conducted the initial research, and later used the samples from the Havasupai to perform unrelated studies, including genetic and medical records analysis of inbreeding, schizophrenia, migration history, and genealogy. The Havasupai sued the University, alleging that it misused their genetic information, and that it conducted research for which it never obtained informed consent. The lawsuit resulted in a large settlement and destruction of the samples. Eriksson, S., and G. Helgesson. (2005).

Chapter 95

GENETIC TESTING: SCIENTIFIC BACKGROUND FOR POLICYMAKERS*

Amanda K. Sarata

ABSTRACT

Congress has considered, at various points in time, numerous pieces of legislation that relate to genetic and genomic technology and testing. These include bills addressing genetic discrimination in health insurance and employment; personalized medicine; the patenting of genetic material; and the quality of clinical laboratory tests, including genetic tests. The focus on these issues signals the growing importance of the public policy issues surrounding the clinical and public health implications of new genetic technology. As genetic technologies proliferate and are increasingly used to guide clinical treatment, these public policy issues are likely to continue to garner considerable attention. Understanding the basic scientific concepts underlying genetics and genetic testing may help facilitate the development of more effective public policy in this area.

Most diseases have a genetic component. Some diseases, such as Huntington's Disease, are caused by a specific gene. Other diseases, such as heart disease and cancer, are caused by a complex combination of genetic and environmental factors. For this reason, the public health burden of genetic disease is substantial, as is its clinical significance. Experts note that society has recently entered a transition period in which specific genetic knowledge is becoming critical to the delivery of effective health care for everyone. Therefore, the value of and role for genetic testing in clinical medicine is likely to increase significantly in the future.

INTRODUCTION

Virtually all disease has a genetic component.¹ The term "genetic disease" has traditionally been used to refer to rare monogenic (caused by a single gene) inherited disease, for example,

* This is an edited, reformatted and augmented version of a Congressional Research Service publication, CRS Report for Congress RL33832, prepared for Members and Committees of Congress, from www.crs.gov, dated December 19, 2011.

cystic fibrosis. However, we now know that many common complex human diseases, including common chronic conditions such as cancer, heart disease, and diabetes, are influenced by several genetic and environmental factors.² For this reason, they could all be said to be “genetic diseases.” Considering this broader definition of genetic disease, the public health burden of genetic disease can be seen to be substantial. In addition, an individual patient’s genetic make-up, and the genetic make-up of his disease, will help guide clinical decision making. Experts note that “(w)e have recently entered a transition period in which specific genetic knowledge is becoming critical to the delivery of effective health care for everyone.”³ This sentiment is still broadly shared, despite the fact that the translation to practice has perhaps been slower than anticipated due to the lack of a comprehensive evidence base to inform clinical validity and utility determinations for many genomic technologies. Experts in the field note that, “[d]espite dramatic advances in the molecular pathogenesis of disease, translation of basic biomedical research into safe and effective clinical applications remains a slow, expensive, and failure-prone endeavor.”⁴ Over time, as translational obstacles are addressed, the value of and role for genetic testing in clinical medicine is likely to increase significantly. As the role of genetics in clinical medicine and public health continues to grow, so too will the importance of public policy issues raised by genetic technologies.

Science is beginning to unlock the complex nature of the interaction between genes and the environment in common disease, and their respective contributions to the disease process. The information provided by the Human Genome Project is helping scientists and clinicians to identify common genetic variation that contributes to disease, primarily through genome-wide association studies (GWAS).⁵ However, researchers have identified a significant translational gap between genetic discoveries and application in clinical and public health practice and note that “the pace of implementation of genome-based applications in health care and population health has been slow.”⁶ Efforts are underway to close this gap and expedite translation into practice, specifically the recent development of the NIH-CDC collaborative Genomic Applications in Practice and Prevention Network.⁷ Experts note that the moderate effect of many common variants, uncovered by GWAS, has helped to underscore the multifactorial etiology of complex disease, and that substantially greater research efforts will be required to detect “missing” genetic influences.⁸ GWAS efforts have identified 1,100 well-validated genetic risk factors for common disease; however, the potential for many of these factors to serve as drug targets is unknown.⁹ In addition, research conducted utilizing large population databases that collect health, genetic, and environmental information about entire populations will likely provide more information about the genetic and environmental underpinnings of common diseases. Many countries have established such databases, including Iceland, the United Kingdom, and Estonia. The knowledge of the potential relevance of genetic information to the clinical management of nearly all patients coupled with the lack of complete information about the genetic and environmental factors underlying disease creates a challenging climate for public policymaking.

In many cases, the results of genetic testing may be used to guide clinical management of patients, and a particularly prominent role is anticipated in the realm of preventive medicine.¹⁰ For example, more frequent screening may be recommended for individuals at increased risk of certain diseases by virtue of their genetic make-up, such as colorectal and breast cancer. In some cases, prophylactic surgery may even be indicated. Decisions about courses of treatment and dosing may also be guided by genetic testing, as might reproductive decisions (both clinical and personal). However, many diseases with an identified molecular cause do not have any

treatment available; specifically, therapies exist only for approximately 200 of the more than 4,000 conditions with a known molecular cause.¹¹ In these cases, the benefits of genetic testing lie largely in the information they provide an individual about his or her risk of future disease or current disease status. The value of genetic information in these cases is personal to individuals, who may choose to utilize this information to help guide medical and other life decisions for themselves and their families. The information can affect decisions about reproduction; the types or amount of health, life, or disability insurance to purchase; or career and education choices. As genetic research continues to advance rapidly, it will often be the case that genetic testing may be able to provide information about the probability of a health outcome without an accompanying treatment option. This situation again creates unique public policy challenges, for example, in terms of decisions about the coverage of genetic testing services and education about the value of testing.

Policymakers may need to balance concerns about the potential use and misuse of genetic information, as well as issues of genetic exceptionalism¹² and genetic determinism¹³, with the potential of genetics and genetic technology to improve care delivery, for example by personalizing medical care and treatment of disease. In addition, policymakers face decisions about the extent of federal oversight and regulation of genetic tests, patients' safety, and innovation in this area. Finally, the need for and degree of federal support for research to develop a comprehensive evidence base to facilitate the integration of genetic testing into clinical practice (for example, to support coverage decisions by health insurers) may be debated. This report will summarize basic scientific concepts in genetics and will provide an overview of genetic tests, their main characteristics, and the key policy issues they raise.

FUNDAMENTAL CONCEPTS IN GENETICS

The following section explains key concepts in genetics that are essential for understanding genetic testing and issues associated with testing that are of interest to Congress.

Cells Contain Chromosomes

Humans have 23 pairs of chromosomes in the nucleus of most cells in their bodies. These include 22 pairs of autosomal chromosomes (numbered 1 through 22) and one pair of sex chromosomes (X and Y). One copy of each autosomal chromosome is inherited from the mother and from the father, and each parent contributes one sex chromosome.

Many syndromes involving abnormal human development result from abnormal numbers of chromosomes (such as Down Syndrome). Other diseases, such as leukemia, can be caused by breaks in or rearrangements of chromosome pieces.

Chromosomes Contain DNA

Chromosomes are composed of deoxyribonucleic acid (DNA) and protein. DNA is comprised of complex chemical substances called bases. Strands made up of combinations of

the four bases (adenine (A), guanine (G), cytosine (C) and thymine (T)) twist together to form a double helix (like a spiral staircase). Chromosomes contain almost 3 billion base pairs of DNA that code for about 20,000-25,000 genes (this is a current estimate, although it may change and has changed several times since the publication of the human genome sequence).¹⁴

DNA Codes for Protein

Proteins are fundamental components of all living cells. They include enzymes, structural elements, and hormones. Each protein is made up of a specific sequence of amino acids. This sequence of amino acids is determined by the specific order of bases in a section of DNA. A gene is the section of DNA which contains the sequence which corresponds to a specific protein. Changes to the DNA sequence, called mutations, can change the amino acid sequence. Thus, variations in DNA sequence can manifest as variations in the protein which may affect the function of the protein. This may result in, or contribute to the development of, a genetic disease.

Genotype Influences Phenotype

Though most of the genome is very similar between individuals, there can be significant variation in physical appearance or function between individuals. In other words, although we share most of the genetic material we have, we can see that there are significant differences in our physical appearance (height, weight, eye color, etc.). Humans inherit one copy (or allele) of most genes from each parent. The specific alleles that are present on a chromosome pair constitute a person's genotype. The actual observable, or measurable, physical trait is known as the phenotype. For example, having two brown-eye color alleles would be an example of a genotype and having brown eyes would be the phenotype.

Many complex factors affect how a genotype (DNA) translates to a phenotype (observable trait) in ways that are not yet clear for many traits or conditions. Study of a person's genotype may determine if a person has a mutation associated with a disease, but only observation of the phenotype can determine if that person actually has physical characteristics or symptoms of the disease. Generally, the risk of developing a disease caused by a single mutation can be more easily predicted than the risk of developing a complex disease caused by multiple mutations in multiple genes and environmental factors. Complex diseases, such as heart disease, cancer, immune disorders, or mental illness, for example, have both inherited and environmental components that are very difficult to separate. Thus, it can be difficult to determine whether an individual will develop symptoms, how severe the symptoms may be, or when they may appear.

GENETIC TESTS

What Is a Genetic Test?

Scientifically, a genetic test may be defined as:

an analysis performed on human DNA, RNA, genes, and/or chromosomes to detect heritable or acquired genotypes, mutations, phenotypes, or karyotypes that cause or are likely to cause a specific disease or condition. A genetic test also is the analysis of human proteins and certain metabolites, which are predominantly used to detect heritable or acquired genotypes, mutations, or phenotypes.¹⁵

Once the sequence of a gene is known, looking for specific changes is relatively straightforward using the modern techniques of molecular biology. In fact, these methods have become so advanced that hundreds or thousands of genetic variations can be detected simultaneously using a technology called a microarray.¹⁶

Policy Issues

The way genetic test is defined can be very important to the development of genetics-related public policy. For example, the above scientific definition is very broad, including both predictive and diagnostic tests and analyses on a broad range of material (nucleic acid, protein, and metabolites), but this may not be the best way to achieve certain policy goals. It may sometimes be desirable to limit the definition only to predictive, and not diagnostic, genetic testing because often, predictive tests raise public policy concerns that diagnostic tests do not (see “What Are the Different Types of Genetic Tests?”). In other cases, it may be desirable to limit the definition to only analysis of specific material, such as DNA, RNA, and chromosomes, but not metabolites or proteins, for example, to help avoid capturing certain types of tests, such as some newborn screening tests, in the scope of a proposed law. Policies extending protection against discrimination may aim to be as broad as possible, whereas policies addressing the stringency of oversight of genetic tests may aim to be more limited (to predictive or probabilistic tests only, or to those for conditions with no treatment, for example).

How Many Genetic Tests are Available?

As of December 2011, genetic tests are available for 2,492 diseases. Of those tests, 2,238 are available for clinical diagnosis, while 254 are available for research only.¹⁷ The majority of these tests are for single-gene rare diseases.

What Are the Different Types of Genetic Tests?

Most clinical genetic tests are for rare disorders, but increasingly, tests are becoming available to determine susceptibility to common, complex diseases and to predict response to medication.

With respect to health-related tests (i.e., excluding tests used for forensic purposes, such as “DNA fingerprinting”), there are two general types of genetic testing: diagnostic and predictive. Genetic tests can be utilized to identify the presence or absence of a disease (diagnostic). Predictive genetic tests can be used to predict if an individual will definitely get a disease in the future (presymptomatic) or to predict the risk of an individual getting a disease in the future (predispositional). For example, testing for mutations in the BRCA1 and/or BRCA2 genes provides probabilistic information about how likely an individual is to develop

breast cancer in his or her lifetime (predispositional). The genetic test for Huntington's Disease provides genetic information that is predictive in that it allows a physician to predict with certainty whether an individual will develop the disease, but does not allow the physician to determine when the onset of symptoms will actually occur (presymptomatic). In both of these examples, the individual does not have the clinical disease at the time of genetic testing, as they would with diagnostic genetic testing.

Within this broader framework of diagnostic and predictive genetic tests, several distinct types of genetic testing can be considered. Reproductive genetic testing can identify carriers of genetic disorders, establish prenatal diagnoses or prognoses, or identify genetic variation in embryos before they are used in *in vitro* fertilization. Reproductive genetic testing, such as prenatal testing, may be either diagnostic or predictive in nature. Newborn screening is a type of genetic testing that identifies newborns with certain metabolic or inherited conditions (although not all newborn screening tests are genetic tests). Traditionally, most newborn screening has been diagnostic, but some states have chosen to add certain predictive genetic testing to their newborn screening panels (for example, Maryland includes testing for cystic fibrosis).¹⁸ Finally, pharmacogenomic testing, or testing to determine a patient's likely response to a medication, may be considered either diagnostic or predictive, depending on the context in which it is being utilized (i.e., before administration of a medication to determine potential effectiveness, dosing levels, or potential adverse interactions or events vs. after administration and manifestation of a clinical event, for use in determining the basis of the specific event or outcome in the particular patient).

Policy Issues

Generally, predictive genetic testing (both presymptomatic and predispositional), rather than diagnostic testing, raises more complex ethical, legal, and social issues. For example, issues surrounding insurance coverage and reimbursement for this type of test, especially if no treatment is available, are more complex than with diagnostic genetic testing. A private insurer may feel that paying for a test that predicts the onset of a disease with no treatment is not cost-effective. Even more complicated are cases where the test only shows an increased probability of getting a disease.

Another issue is the oversight of genetic tests. Decisions about the need for oversight of genetic testing may be based on whether the information they provide is probabilistic rather than diagnostic, and whether a treatment is available. Additionally, stronger regulation of direct-to consumer marketing of genetic tests, or direct access testing,¹⁹ may be desirable in cases where a test is probabilistic rather than diagnostic.

Finally, issues of genetic discrimination may be different with predictive testing than they are with diagnostic testing. Genetic discrimination may be defined as differential treatment in either health insurance coverage or employment based upon an individual's genotype. Discriminatory action based on the possibility of something happening in the future, or even the certainty of it happening in the future, might raise more concern than would action taken based upon diagnostic information. With probabilistic genetic information (generated by predictive testing, see above), the health outcome at issue may never manifest, or if it is certain to, may not manifest for decades into the future. An individual's concern about the privacy of her genetic information may also be different if the information is probabilistic. For example, an individual who tests positive for being at increased risk of developing breast cancer in the future might believe unfavorable insurance or employment decisions based on this information

in the present (when she does not have breast cancer) would be unfair. If this were in fact her belief, this individual may have heightened concern with keeping this information private from health insurers or employers.

The Genetic Test Result

Genetic tests can provide information about both *inherited* genetic variations, that is, the individual's genes that were inherited from their mother and father, as well as about *acquired* genetic variations, such as those that cause some tumors. Acquired variations are not inherited, but rather are acquired in DNA due to replication errors or exposure to mutagenic chemicals and radiation (e.g., UV rays). In contrast with most other medical tests, genetic tests can be performed on material from a body, and may continue to provide information after the individual has died, as a result of the stability of the DNA molecule.

DNA-based testing of inherited genetic variations differs from other medical testing in several ways. These test results can have exceptionally long-range predictive powers over the lifespan of an individual; can predict disease or increased risk for disease in the absence of clinical signs or symptoms; can reveal the sharing of genetic variants within families at precise and calculable rates; and, at least theoretically, have the potential to generate a unique identifier profile for individuals.

Genetic changes to inherited genes can be acquired throughout a person's life (acquired genetic variation). Tests that are performed for acquired genetic variations that occur with a disease have implications only for individuals with the disease, and not family members. Tests for acquired genetic variations are also usually diagnostic rather than predictive, since these tests are generally performed after the presentation of symptoms.

Pharmacogenomic testing may be used to determine *both* acquired genetic variations in disease tissue (i.e., acquired variations in a tumor) or may be used to determine inherited variations in an individual's drug metabolizing enzymes. For example, with respect to determining acquired genetic variations in disease tissue, a tumor may have acquired genetic variations that render the tumor susceptible or resistant to chemotherapy. With respect to inherited genetic variation in drug metabolizing enzymes, an individual may, for example, be found to be a slow metabolizer of a certain type of drug (e.g., statins) and this information can be used to guide both drug choice and dosing.

Policy Issues

In some cases, people feel differently about their genetic information than they do about other medical information, a sentiment embodied by the concept of genetic exceptionalism. This viewpoint may be based on actual differences between genetic testing and other medical testing, but also may be based on personal belief that genetic information is powerful and different than other medical information. For example, genetic information about an individual may reveal things about family members, and therefore decisions by an individual to share her own genetic information can potentially also affect her family. Partially as a result of these considerations, the 110th Congress passed the Genetic Information Nondiscrimination Act of 2008 (P.L. 110-233), and many states, beginning in the early 1990s, enacted laws addressing genetic discrimination in health insurance, employment, and life insurance. Whether genetic

information is in fact different from other medical information and whether it deserves special protection are important public policy issues.²⁰

Pharmacogenomic testing is important because it will help provide the foundation for personalized medicine. Personalized medicine is healthcare based on individualized diagnosis and treatment for each patient determined by information at the genomic level. Many public policy issues are associated with personalized medicine. For example, there is some uncertainty currently as to how health insurers will assess and choose to cover pharmacogenomic testing as it becomes available. In addition, there are issues surrounding the regulation of pharmacogenomic testing and the encouragement of the co-development of drugs and diagnostic genetic tests (companion diagnostics). Companion diagnostics guide the use of the drug in a given individual.

Characteristics of Genetic Tests

Genetic tests function in two environments: the laboratory and the clinic. Genetic tests are evaluated based primarily on three characteristics: analytical validity, clinical validity, and clinical utility.

Analytical Validity

Analytical validity is defined as the ability of a test to detect or measure the analyte it is intended to detect or measure.²¹ This characteristic is critical for all clinical laboratory testing, not only genetic testing, as it provides information about the ability of the test to perform reliably at its most basic level. This characteristic is relevant to how well a test performs in a laboratory.

Clinical Validity

The clinical validity of a genetic test is its ability to accurately diagnose or predict the risk of a particular clinical outcome. A genetic test's clinical validity relies on an established connection between the DNA variant being tested for and a specific health outcome. Clinical validity is a measure of how well a test performs in a clinical rather than laboratory setting. Many measures are used to assess clinical validity, but the two of key importance are clinical sensitivity and positive predictive value. Genetic tests can be either diagnostic or predictive and, therefore, the measures used to assess the clinical validity of a genetic test must take this into consideration. For the purposes of a genetic test, positive predictive value can be defined as the probability that a person with a positive test result (i.e., the DNA variant tested for is present) either has or will develop the disease the test is designed to detect. Positive predictive value is the test measure most commonly used by physicians to gauge the usefulness of a test to clinical management of patients. Determining the positive predictive value of a predictive genetic test may be difficult because there are many different DNA variants and environmental modifiers that may affect the development of a disease. In other words, a DNA variant may have a known association with a specific health outcome, but it may not always be causal. Clinical sensitivity may be defined as the probability that people who have, or will develop a disease, are detected by the test.

Clinical Utility

Clinical utility takes into account the impact and usefulness of the test results to the individual and family and primarily considers the implications that the test results have for health outcomes (for example, is treatment or preventive care available for the disease). It also includes the utility of the test more broadly for society, and can encompass considerations of the psychological, social, and economic consequences of testing.

Policy Issues

These three above-mentioned characteristics of genetic tests, or analytic validity, clinical validity, and clinical utility, have important ties to public policy issues. For example, although the analytical validity of genetic tests is regulated by the Centers for Medicare and Medicaid Services (CMS) through the Clinical Laboratory Improvement Amendments (CLIA) of 1988 (P.L. 100- 578), the clinical validity of the majority of genetic tests is not regulated at all. This has raised concerns about direct-to-consumer marketing of genetic tests where the connection between a DNA variant and a clinical outcome has not been clearly established. Marketing of such tests to consumers directly may mislead consumers into believing that the advice given them based on the results of such tests could improve their health status or outcomes when in fact there is no scientific basis underlying such an assertion. This issue was the subject of a July 2006 hearing by the Senate Special Committee on Aging. In addition, clinical utility and clinical validity both figure prominently into coverage decisions by payers, but a lack of data often hinders coverage decisions, potentially leaving patients without coverage for these tests.

Coverage by Health Insurers

Health insurers are playing an increasingly large role in determining the availability of genetic tests by deciding which tests they will pay for as part of their covered benefit packages. Many aspects of genetic tests, including their clinical validity and utility, may complicate the coverage decision-making process for insurers. While insurers require that, where applicable, a test be approved by the Food and Drug Administration (FDA), they also want evidence that it is “medically necessary;” that is, evidence demonstrating that a test will affect a patient’s health outcome in a positive way. This additional requirement of evidence of improved health outcomes underscores the importance of patient participation in long-term research in genetic medicine. Particularly for genetic tests, data on health outcomes may take a very long time to collect.

Policy Issues

Decisions by insurers to cover new genetic tests have a significant impact on the utilization of such tests and their eventual integration into the health care system. The integration of personalized medicine into the health care system will be significantly affected by coverage decisions. Although insurers are beginning to cover pharmacogenomic tests and treatments, the high cost of such tests and treatments often means that insurers require stringent evidence that they will improve health outcomes. As mentioned previously, this evidence is often lacking.

In addition, coverage of many genetic tests and services, which may be considered preventive in some cases, might be affected by the passage of the Patient Protection and

Affordable Care Act of 2010 (ACA, P.L. 111-148). The ACA requires private health insurers, Medicare, and Medicaid to cover clinical preventive services (as specified in the law) and outlines cost-sharing requirements in some cases for these services.²² However, the ACA provisions in some cases tie coverage of clinical preventive services to determinations by the U.S. Preventive Services Task Force (USPSTF, located in the Agency for Healthcare Research and Quality), and these determinations are based on the quality of the evidence available to support a given clinical preventive service. For this reason, coverage of genetic tests and services (that are determined to be preventive clinical services) might be negatively affected by a lack of high-quality evidence to support their use.

Regulation of Genetic Tests by the Federal Government

Genetic tests are regulated by the Food and Drug Administration (FDA) and CMS, through CLIA. FDA regulates genetic tests that are manufactured by industry and sold for clinical diagnostic use. These test kits usually come prepackaged with all of the reagents and instructions that a laboratory needs to perform the test and are considered to be products by the FDA. FDA requires manufacturers of the kits to ensure that the test detects what the manufacturer says it will, in the intended patient population. With respect to the characteristics of a genetic test, this process requires manufacturers to prove that their test is clinically valid. Depending on the perceived risk associated with the intended use promoted by the manufacturer, the manufacturer must determine that the genetic test is safe and effective, or that it is substantially equivalent to something that is already on the market that has the same intended use.

Most genetic tests, however, are performed not with test kits, but rather as laboratory testing services (referred to as either laboratory-developed or “homebrew” tests), meaning that clinical laboratories themselves perform the test in-house and make most or all of the reagents used in the tests. Laboratory-developed tests (LDTs) are not currently regulated by the FDA in the way that test kits are and, therefore, the clinical validity of the majority of genetic tests is not regulated. The FDA does regulate certain components used in LDTs, known as Analyte Specific Reagents (ASRs), but only if the ASR is commercially available. If the ASR is made in-house by a laboratory performing the LDT, the test is not regulated at all by the FDA. This type of test is sometimes referred to informally as a “homebrew-homebrew” test.

Any clinical laboratory test that is performed with results returned to the patient must be performed in a CLIA-certified laboratory. CLIA is primarily administered by CMS in conjunction with the Centers for Disease Control and Prevention (CDC) and the FDA.²³ FDA determines the category of complexity of the test so the laboratories know which requirements of CLIA they must follow. As previously noted, CLIA regulates the analytical validity of a clinical laboratory test only. It generally establishes requirements for laboratory processes, such as personnel training and quality control or quality assurance programs. CLIA requires laboratories to prove that their tests work properly, to maintain the appropriate documentation, and to show that tests are interpreted by laboratory professionals with the appropriate training. However, CLIA does not require that tests made by laboratories undergo any review by an outside agency to see if they work properly. Supporters of the CLIA regulatory process argue that regulation of the testing process gives the laboratories optimal flexibility to modify tests

as new information becomes available. Critics argue that CLIA does not go far enough to assure the accuracy of genetic tests since it only addresses analytical validity and not clinical validity.

ABSTRACT

The advent of massively parallel sequencing has changed the interrogation process of the human genome and now provides a high resolution and global view of the genome which is beyond research applications. Together with powerful bioinformatics tools, these next generation sequencing technologies have revolutionized fundamental research and have important consequences for clinically actionable tests, diagnosis and treatment of rare diseases and cancers. Today, molecular testing is commonly used to confirm clinical diagnosis of specific diseases; it requires that a clinician specify the gene or mutation to test and, in return, will receive information only about this sequence. Despite relative successes, a large number of patients receive no accurate diagnosis, even after many expensive molecular investigations. A clear paradigm shift has taken place in the health network with the introduction of the exome sequencing in molecular diagnostic lab. In this chapter, the impact of the implementation of high throughput sequencing technologies on molecular diagnosis and on the practice of medicine, with an emphasis in paediatrics, is reviewed. We compared well-established genetic tests, using examples from our molecular diagnostic lab, to the recent exome sequencing applications. The genetic tests can fall into three main categories: 1) Mendelian Single Gene Disorder tests that include targeted mutation and targeted gene approaches 2) Genetic Disease Panels which are composed of a few to a dozen genes and 3) Exome or Genome approaches, which interrogate either the

* Corresponding Author's Email: julie.gauthier@recherche-ste-justine.qc.ca.

entire coding sequences of the 22,333 human genes or the entire human genome. For each of these categories, advantages and limitations are discussed. We devoted a section on the future of molecular diagnosis and discuss which tests will subsist and which one may be soon abandoned. Massively parallel sequencing is transforming the molecular diagnostic field: it offers personalized genetic tests and generates new ethical challenges. Important questions like incidental findings and possible forms of discrimination are addressed. Finally, we conclude with a section on the future directions surrounding the application of these multimodal molecular approaches in general and their putative applications in neonatal intensive care units.

1. INCREASED HUMAN GENOME KNOWLEDGE THROUGH PROGRESS IN SEQUENCING TECHNOLOGY

Sequencing the DNA of an organism is feasible since 1977 when the "dideoxy" chain-termination method for sequencing DNA molecules was introduced by Frederick Sanger and colleagues [1]. This technique allows for the sequencing of a single DNA fragment up to 1000 base pairs long. The original method used radiolabeled dNTP and the reading was done manually. Sanger sequencing has been the basis of several major gene discoveries transforming the field of molecular biology. For example, before DNA sequencing, proteins were sequenced directly, this is a laborious technique. Now, this is easily accomplished by sequencing a cDNA and translating the DNA sequence into the amino acid sequence of the protein. In the early 1990s, DNA sequencing was automated using a 4-channel capillary approach (basically the current Life Technologies ABI 3730 system) and ddNTP labeled with different color fluorescent dyes which allow fast DNA sequencing, with hundreds of fragments simultaneously. These sequencing systems were the first generation of sequencing technologies. Their high-throughput yield allows a single lab to sequence millions of base pairs, compared to thousands before their introduction. Commonly called the Sanger method, this sequencing technique is the gold standard in research and clinical diagnostic laboratories for genetic testing. This advance in technology led to science's greatest achievement, the Human Genome Project. This project aimed to determine the sequence of the 3 billion nucleotide base pairs that constitute the human genome and to identify all 22,333 genes [2] in human DNA [3]. This 13-year project gave rise to the first draft of the human genome sequence in 2001. Decoding the human genome has opened unprecedented new avenues in research and increased our understanding of human health. Information from the human genome sequence enables us to understand how the genetic information drives the development and function of the human body. More importantly, the Human Genome Project accelerated the exploration of genetic variations predisposing to disease and thus revolutionizes medical practice and biological research. Since then, the availability of genomic information (gene and chromosome structure, polymorphisms, disease causing mutations, etc.), has continuously increased.

Sanger sequencing helped the discovery of new genetic mechanisms. For example, by sequencing more than 400 synaptic genes in affected probands with sporadic schizophrenia or autism (that is, with no history of psychiatric disorders in the parents or the extended family), we and others have observed a significant excess of potentially deleterious *de novo* mutations in affected individuals [4]. A similar observation was done in intellectual disability cases [5].

The most recent DNA sequencing development is the advent of massively parallel sequencing platforms leading to the “next generation sequencing” technologies. The development of ultra-high throughput sequencing technologies pushed forward at an unprecedented speed the identification of DNA variations associated with diseases. Ultrasequencing platforms can be combined with microarray technologies to capture and amplify the functional genome that encodes proteins, also known as the “exome”, or to capture more comprehensively a subset of related genes. As technology progressed, next-generation DNA sequencing techniques have improved significantly and are now much faster, and to some extent less expensive than Sanger sequencing. What took over 10 years like the Human Genome Project can now be done in less than a month. It’s now feasible to decode multiple human genomes at once. All of these progresses gave birth to larger scale genetics.

A remarkable increase of genetic and genomic data occurred in the last decade notably through the introduction of microarrays and next-generation sequencing. In fact, human genome array-comparative genomic hybridization and SNP arrays were developed to detect genetic aberrations or copy number variants (CNVs) at a higher resolution than traditional karyotyping. Comparative genomic hybridization, also called array CGH, is now currently used in diagnostic labs to identify small chromosomal deletions and duplicated regions. For example, conventional karyotyping has a resolution of 5-10 million bases compare to 100 000 for array-CGH. Therefore, submicroscopic chromosomal alterations can now be detected. These technological progresses lead researchers to major discoveries in the understanding of genetic mechanisms of different neuropsychiatric conditions such as intellectual disabilities, autism and schizophrenia. De Vries et al. used array based comparative genomic hybridization (array CGH) to study 100 patients with unexplained intellectual disability. They were able to detect a potential causative chromosomal anomaly in 10% of their patients which represents a diagnostic yield of at least twice as high as that of conventional method [7]. In addition to the identification of the causative genetic factors implicated in pediatric and childhood complex disorders, microarrays initiated the discovery of new genetic mechanisms for a number of complex disorders, namely autism, intellectual disability and schizophrenia. Using these technologies, studies have highlighted the involvement of rare (<1% frequency) point mutations and CNVs in the genetic etiology of autism, schizophrenia, intellectual disability, attention deficit disorder and other disorders [6-9].

Molecular diagnostics has become an essential tool for the evaluation and management of patients, particularly of children with genetic diseases. According to the Online Mendelian Inheritance in Man (OMIM), an online catalog of human genes and genetic disorders, more than 3,807 diseases (the majority >2,500 being rare) have been characterized at the molecular level, and for over 3,500 of these the genetic causes are still unknown. Some genetic conditions are related to a single gene (e.g., cystic fibrosis), but most genetic diseases are characterized by a great heterogeneity, each of which can be caused by mutations in one of several genes (Intellectual disability > 300 genes, Deafness > 60 genes, Mitochondrial diseases >300 genes). The current molecular diagnosis of clinical phenotypic heterogeneity in genetic conditions is laborious and expensive because it involves the sequential analysis of several genes.

2. THE GENETIC DIAGNOSIS: A MULTI TECHNICAL APPROACH FOR NEURODEVELOPMENTAL AND METABOLIC DISORDERS

The advance of modern genomics has changed the health economic decisions concerning genetic screening, with costs- per-megabase for DNA sequencing falling at a faster rate than predicted. Although individually rare, Mendelian diseases collectively account for a significant percentage of infant mortality and pediatric hospitalizations [10]. The speed with which genomics is becoming clinically relevant and the increasing power of the new sequencing technologies led to its rapid implementation in clinical settings. Assuming that new technology automatically translates into improved patient care is idealistic.

The ability to amplify DNA by polymerase chain reaction (PCR) has revolutionized our ability to test for genetic mutations. Many different assay systems are based on PCR for analyzing the amplified DNA or RNA. These techniques are sensitive, reliable and can be performed easily on different material: blood, skin or muscle biopsies, tumour, foetus, and even single cells from blastomeres and polar bodies. The aims of adapting new PCR-based strategies in clinical settings are improving the accuracy, speeding up the diagnosis, the time-consuming and costing without decreasing the sensitivity or specificity. Understanding the type of mutations, the incidence of *de novo* mutations or genetic rearrangements is essential to accurately select the best molecular technique for the detection of carrier in pre-natal diagnosis. Techniques involving PCR-based amplification are successfully used for mutation screening in the majority of diseases. It can be combined for the detection of the presence or absence of restriction sites, electrophoretic mobility shift or sizing analysis, as in single strand conformation polymorphism (SSCP) or in denaturing gradient gel electrophoresis (DGGE). Computer-assisted highly sensitive mutation detection is also performed, for the above techniques, by means of fluorescent PCR for allelic specific discrimination. Recent advances in the development of quantitative real-time PCR (qPCR)-based diagnostic tools allow detection and quantification of gene or exon dosage.

An alternative procedure to mutation-directed protocols for complex genetic mutations is the use of fluorescent multiplex PCR. Indirect diagnosis performed by the use of polymorphic microsatellite markers, allowing identification of the pathogenic haplotype instead of the mutation [11, 12] as for instance in some spinal muscular atrophy or Duchenne muscular dystrophy families. For diseases involving a heterogeneous spectrum of identified mutations, such as cystic fibrosis, autosomal non-syndromic intellectual disability (*SYNGAP1*) or Rett Syndrome (*MECP2*), the development of a mutation-based strategy is not practical and sequencing of the entire coding sequence is recommended to facilitate mutation detection.

Multiplex ligation-dependent probe amplification (MLPA) is a variation of the multiplex polymerase chain reaction that permits multiple targets (exons) to be amplified with only a single primer pair [13]. Specific fluorescent probes consist of two unique oligonucleotides which recognise adjacent target sites on the DNA and each amplicon generates a fluorescent peak which can be detected by a capillary sequencer. Comparing the peak pattern obtained on a given sample with those obtained on various control samples, allow the relative quantity of each target to be determined. This technique is commonly used to detect chromosomal anomalies in cell and tissue samples, [14] detection of gene copy number [13], detection of duplications and deletions in disease-related genes such as *DMD*, *MECP2*, *BRCA1*, *BRCA2*, etc. It has replaced the need to use of southern blot in many diseases [15-17].

Expansion repeat disorders such as of the glutamine codon (CAG) in spinocerebellar ataxias, or the trinucleotide repeat in non-coding regions, as the CGG in Fragile-X syndrome, the GAA in Friedreich ataxia or the CTG in myotonic dystrophy type I, are a special type of mutation. The unstable dynamic nature of those mutations requires the use of a multimodal approach [18]. Molecular tests for the diagnosis and carrier detection often combine PCR for the repeat expansion and triplet repeat primed PCR (TP-PCR) analysis of genomic DNA, as well as southern blot.

The detection rate of the screening test, as well as the frequency of the mutation in the study population and the technical limitations of the procedure, will determine the usefulness of a positive or negative result. Preimplantation testing provides a paradigm for the ease of use of PCR-based testing, yet also underscores the problems encountered with genetic screening because of the multitude of possible mutations and the possible misinterpretation of results [12].

Molecular diagnostic testing is currently available for only a certain number of disorders and with the increasing number of new genes associated to human diseases, it is becoming more and more challenging to provide cost effective molecular testing [10]. Preconception screening, together with genetic counselling of carriers, has resulted in remarkable declines in the incidence of several severe recessive diseases in populations at risk [19, 20]. However, extensive preconception screening and molecular diagnostic testing has been limited to targeted population or family history-directed individual and is still impractical for many disorders [20].

2.1. Mendelian Single Gene Disorders: At the Mutation or Gene Level

Single-gene disorders have a straight forward inheritance pattern, and the genetic causes can be traced to changes in specific individual genes. A particular disorder may be rare; however, as a group of disease-causing genes, single-gene disorders are responsible for a significant percentage of pediatric diseases [21]. About 1% of the approximately 4 million annual live births in the United States will have a single gene disorder that requires intensive clinical investigation, specific medical treatment and hospitalization [22, 23]. Based on the location of the relevant genes, single-gene traits can be divided into autosomal or sex-linked inheritance. Autosomal inheritance, depending on whether one or two mutant alleles are required to cause the disease phenotype, can be classified as autosomal dominant or autosomal recessive. Each of these single gene disorders, called Mendelian traits or diseases, are relatively uncommon. The frequency often varies with ethnic background, with each ethnic group having one or more Mendelian traits in higher frequency when compared to the other ethnic groups. For example, cystic fibrosis has a frequency of about one in 2,000 births in Americans descended from western European Caucasians [10] but is much rarer in African-Americans descent while sickle cell anemia has a frequency of about 1/600 births in African-American, but is rare in Caucasians [24]. Just to name a few, Mediterranean descent have a high frequency of thalassemia [25]; Eastern European Jews have a high frequency of Tay-Sachs disease [26, 27]; French Canadians from Quebec have a high frequency of tyrosinemia [28], all when compared to other ethnic groups. It has been estimated, regardless of the ethnicity, that each healthy individual is carrying between 1 and 8 mutations which, if found in the homozygous state would result in the expression of a Mendelian recessive disease [10]. Since each human genome has 22,333 genes it is unlikely that any two unrelated individuals would be carrying

the same mutations, even if they are from the same ethnic background. This explains why most Mendelian diseases are rare, affecting about 1/10,000 to 1/100,000 live births [21, 29].

In Quebec, the distribution of Mendelian diseases is due to local founder effects caused by the stratification of the contemporary French Canadian gene pool. The migration of a small number of French individuals from France to Quebec created a founder effect. Subsequent inland migrations have created smaller regional founder effects [30, 31]. The limited size of the population favoured genetic drift, and the social context encouraged endogamy, only few unions were reported between French Canadians with English and other immigrants [31]. The French-Canadian population of Quebec, currently about 6 million people, descends from about 7,798 immigrant founders who arrived in Quebec between 1608 and 1759 [31]. Recent studies showed that the Quebec population structure through the analysis of the genetic contribution of the first French settlers can be partitioned in eight regions, and they contributed to over 90% of gene pools in seven out of those eight regions [32]. This particular local genetic effect highlights the importance of considering the geographic origin of samples in the design of genetic testing in Quebec [33]. The conditions under which the peopling of Quebec was made, have favoured changes in the frequency of certain alleles in comparison with the French original population. As a result, certain genetic diseases are specific or more prevalent to the Quebec population. The prevalence and distribution of genetic diseases in Quebec is an essential factor to consider in clinical practice and particularly in differential diagnostic to prioritize molecular investigations [20].

This founder effect has impacted our molecular diagnostic testing system and is still a key factor when developing new diagnostic test for a genetic disease. The prevalence of the disease and the nature of the mutations found in the Quebec population need to be taken into account. The performance of the test depends on how well it accounts for the particularities of the disease in the French Canadians but more specifically depending on the regional founder effect [31]. The current changes in the immigration and the increased admixture is bringing new challenges in the differential diagnosis and amelioration of our molecular genetic testing system.

Over thirty Mendelian diseases have a high prevalence in the Quebec population [31, 34, 35]. Before the advances in sequencing technologies, it was believed that some of the disease were almost exclusive to the French Canadians, as autosomal recessive spastic ataxia of Charlevoix-Saguenay (ARSACS; MIM 270550), hereditary motor and sensory neuropathy with agenesis of the corpus callosum (ACCPN; MIM 218000) or French-Canadian-type Leigh syndrome (MIM 220111) [36-38]. Taking ARSACS as an example, after extensive resequencing of the responsible gene, SACS, it became evident that ARSACS was not limited to Quebec, and more than 100 different pathogenic mutations have now been identified worldwide [39, 40]. ARSACS is believed to be underdiagnosed in patients with atypical phenotypes and recent data on exome sequencing suggest a presumably high frequency of allele carriers around the world [39-42].

Admixture has more and more impact on the genetic characteristics of disease in French Canadians. Other ethnic groups have deep roots in the province. Many immigrant communities that are established mainly in and near Montreal now account for over 15% of the Quebec population. First Nations groups in Quebec have specific genetic diseases with three autosomal recessive conditions that have been well documented: Cree leukoencephalopathy [MIM 603896], Cree encephalitis [MIM 608505], North American Indian Childhood Cirrhosis [MIM 604901]. In Cree communities, the carrier frequency of Cree leukoencephalopathy is estimated at 1/10, 1/30 for Cree encephalitis and, 9/100 for the North American Indian Childhood

Cirrhosis [43, 44]. However, universal screening is currently offered only in the neonatal period for phenylketonuria, tyrosinaemia type I, medium-chain acyl-coenzyme A dehydrogenase deficiency [MCAD] and congenital hypothyroidism in addition to selected inborn errors of metabolism by urine screening [45, 46]. Effective targeted carrier-screening programs are provided in some specific communities but are often limited to individuals with a family history of recessive diseases. For public health, the genetic structure of Quebec presents major challenge for genetic screening but brings also opportunities for gene identification studies, clinical genetics research and practice. In the next section, we will discuss our experience over time with the implementation of effective targeted genetic testing and carrier-screening programs.

2.1.1. Targeted Mutations

The French-Canadian population of Quebec evolved as a mosaic of layered founder effects which has stimulated the development and feasibility of population-based carrier screening for at-risk individuals. For most of the Mendelian diseases in Quebec, the mutant founder alleles are characteristic and often unique. Usually one or two founder mutations account for 90% of French-Canadian alleles, depending on the region. However, founder mutations panels do exist for some disorders in Quebec such as for familial hypercholesterolemia, hereditary breast cancer, etc.

A good example of a mutant founder allele in Quebec is the Cree encephalitis, a severe early-onset progressive neurological disorder in an inbred Canadian Aboriginal community [MIM 608505]. The symptoms appear within the first few weeks of life and children usually die in infancy or early childhood. The main neurological symptoms are acquired microcephaly, mental retardation, cerebral atrophy with white matter changes, cerebral calcification, and chronic cerebrospinal fluid lymphocytosis. Cree encephalitis shows phenotypic overlap with Aicardi-Goutières syndrome with elevated levels of IFN- α in cerebrospinal fluid [47, 48]. The gene responsible, named *TREX1* (3-prime repair exonuclease 1, MIM 606609), has only one coding exon and is located on 3p21.31. The mutation causing Cree encephalitis is the p.Arg164Ter (c.490C>T) [49]. The molecular genetic diagnosis consists of determining the presence or absence of p.Arg164Ter in symptomatic patients. CREE encephalitis is among the leading causes of death of Cree infants. Cree carrier rates of this mutation are estimated to be 2-3 individual out of twenty meaning that about one in 300 births will be affected.

In 2006, a genetic screening program was developed and managed by the Cree Health Board to identify carriers of the mutation p.Arg164Ter in the *TREX1* gene. A second autosomal recessive condition is included in the Cree population genetic screening, Cree leukoencephalopathy [MIM 603896]. All patients are homozygous for the mutation p.Glu584Ala in the translation-initiation factor *EIF2B5* gene causing childhood ataxia with central hypomyelination and vanishing white matter disease [CACH/VWM] [50]. Both tests are performed in our molecular diagnostic laboratory at CHU Sainte-Justine. To date, >500 individuals have been tested. Pregnant woman and teenagers in High School are the targeted population for this genetic test. In fact, the rate of teenage pregnancy is very high in Cree population (23% among those aged <20, compared to 4.7% for the rest of Quebec).

Another autosomal recessive disorder caused by a founder mutation in Quebec is the Spastic ataxia of Charlevoix-Saguenay, more commonly known as ARSACS [MIM 270550]. This condition was first observed in people of the Charlevoix-Saguenay region of Quebec, Canada [51]. ARSACS is a debilitating progressive childhood neurological disorder affecting

the spinal cord and peripheral nerves. Most patients become wheelchair-bound but cognitive function is usually not affected. The incidence of ARSACS in the Charlevoix-Saguenay region of Quebec is estimated to be 1 in 1,500 to 2,000 individuals. Genetically confirmed cases of ARSACS have now been described in Italy, Spain, Tunisia, France, Belgium, Hungary, Morocco, Turkey, Serbia, other provinces of Canada, Netherlands, United Kingdom, Algeria and Japan. Therefore, ARSACS has a worldwide distribution but its prevalence in most countries is still unknown, except in the Netherlands where it may be as frequent as Friedreich Ataxia [52]. ARSACS is caused by mutations in the gene encoding the SACSIN protein (SACS) located on 13q12.12. Two major mutations were described in the Charlevoix-Saguenay region of Quebec representing 96,3% of the cause of ARSACS. Other types of mutation such as large deletion of 1.54 MB have been reported in some cases [53].

For carrier status genetic testing at the mutation level is the most appropriate method. However, with the growing number of clinically presumed ARSACS cases with a single mutation or no mutations identified, a systematic search for novel SACS point mutations and genomic rearrangements for the diagnosis of ARSACS is recommended. Recent reports demonstrated the clinical and genetic heterogeneity among ARSACS patients, now considered to be a common form of spastic ataxia worldwide, the challenge required a multimodal approach to rapidly screen larger numbers of samples and enable detection of both point mutations and deletions. Testing at the mutation level is no longer the optimal method with the exception of individuals with a clear genealogy to the Charlevoix Saguenay region of Quebec.

2.1.2. Targeted Gene

Rett Syndrome (RTT) is one of the most common causes of severe intellectual disability in females, with an incidence of 1:12,500 female live births. Most RTT cases are sporadic with no familial history of the disease. We now know that the majority of RTT patients have a *de novo* mutation in the X-linked gene methyl CpG binding protein 2 (*MECP2*) [54]. Very few families with multiple affected individuals, typical siblings, with Rett Syndrome have been described (for examples [55, 56]) where asymptomatic transmitting mothers have skewed X-chromosome inactivation [56], or parental gonadal mosaicism [57]).

Based on the RettBASE IRSF *MECP2* Variation Database, a database merging mutations and polymorphism data, there are more than 4,000 reported different variants in *MECP2* gene. Given that mutation in any of the 4 exons of *MECP2* can lead to the disease, the targeted gene screening approach is necessary for molecular diagnosis purpose. The same approach is used for autosomal non-syndromic intellectual disability and *SYNGAP1* gene [58].

2.2. Genetic Disease Panels: The Intermediate Decision

In recent years, there has been increasing recognition of the importance of inherited gene mutations as a cause of neurodevelopmental and metabolic diseases. Substantial progress has been made in elucidating the molecular defects underpinning these diseases, but the impact of these discoveries on clinical management is often unclear and the increasing number of genes associated with these features causes limitations of testing. The clinical spectrum of these diseases is vast and non-specific phenotype presentations are frequent.

In 1975, at the initiative of Dr Charles Scriver, the Province of Quebec implemented an integrated program for the diagnosis, counseling and treatment of hereditary metabolic diseases. Similar programs were implemented worldwide in order for physicians not to miss a treatable disorder. Clinical expression can be acute or systemic or can involve a specific organ, and can strike in the neonatal period or later and intermittently from infancy to late adulthood. During the last half century, many new disorders have been discovered and many therapeutic procedures have been tried. Some have been life-saving; others are still experimental. The long-term outcome of patient with metabolic patients is variable and requires multidisciplinary management and treatment [59, 60]. Several factors can impact on the availability and utility of genetic panel testing, such as access to testing, cost of testing and the mutation detection rate. There are over 100 different inborn errors of metabolism, including all the disorders detected by expanded newborn screening for which genetic causes have been identified. Traditionally the inherited metabolic diseases were categorized as disorders of carbohydrate metabolism, amino acid metabolism, organic acid metabolism or lysosomal storage diseases [61]. In recent decades, hundreds of new inherited disorders of metabolism have been discovered and the categories have proliferated. Genetic testing is also indicated in some multisystem disorders with frequent metabolic involvement, however genetic testing is not so straightforward for many of the other conditions. The overall incidence of the inborn errors of metabolism were estimated to be 70 per 100,000 live births or 1 in 1,400 [62]. As the number of inherited metabolic diseases that are included in state-based or province newborn screening programs continues to increase, ensuring the quality and delivery of testing services remain a continuous challenge. The vast majority of inborn errors of metabolism are inherited in an autosomal recessive manner. In the case of diseases carried on the X chromosome, males are usually more severely affected because they have only one copy. Females who have one X chromosome with the gene defect and one without may or may not develop symptoms.

Multi-exon or gene panel testing has proven efficient in cystic fibrosis (mutation panels; focussing on exon 6, 12, 23, 40, 97, 102 etc.) in the form of Ashkenazi disease panels and in the Charlevoix-Saguenay disease panel as described in the previous section. Now, molecular diagnostic laboratories offer panels for Comprehensive Carrier Screen Panels (comprising 80 – 100 conditions, between 350 – 500 variants). This multi-gene panel testing is becoming more and more advantageous for heterogeneous disorders such as the inborn inherited metabolic disorders. Historically, the development of carrier panels or diagnostic testing panels was subject to the recommendation of professional committees such as the American College of Medical Genetics and Genomics (ACMG) and the College of American Pathologists (CAP). Disease selection for the development of a diagnostic testing panel must take several points into consideration; 1) the disorder is clinically severe, 2) there is a high frequency of carriers in the screened population, 3) the availability of a reliable test with a high specificity and sensitivity, 4) the availability of prenatal diagnosis & access to genetic counselling, 5) genes recommended for screening by ACMG, 6) Autosomal recessive, X-linked diseases or with high de novo mutation rate [63-65].

As another example of multi-gene testing panel, in the past years, several comparative genomic hybridization studies have suggested recurrent rearrangements in synaptic and neurodevelopment genes. Rare CNVs at numerous loci are involved in the cause of mental retardation, autism, and schizophrenia [66-69]. In addition to those, Angelman syndrome and RTT have significant phenotypic overlap, including acquired microcephaly, loss of purposeful movements, developmental delay or intellectual disability and autistic behaviours. Additional

features include scoliosis, epilepsy, poor growth or obesity, and irregular breathing. There is also a broad clinical variability in the severity of the disease [70, 71]. *MECP2* mutations are present in 70-90% of females with classic RTT and approximately 20% of females with atypical RTT [72]. Partial deletions of *MECP2* are found in approximately 16% of girls with classic or atypical RTT. *CDKL5* mutations have been demonstrated in a broad spectrum of phenotypes including atypical RTT with infantile spasms [73]. Mutations of the *MEF2C* gene have been identified in patients with severe mental retardation, stereotypic movements, hypotonia, and epilepsy [74]. Abnormalities of the *FOXG1* gene have been identified in patients with the congenital variant of RTT [75]. Patients with the congenital variant of RTT have clinical features similar to classic RTT, but hypotonia and severe developmental delay starts in the first months of life [75]. Phenotypic overlap exists between patients with RTT/Angelman or atypical RTT led to a recommendation for sequencing all coding exons and the intron/exon boundaries of *MECP2*, *CDKL5*, *MEF2C*, and *FOXG1* as well as deletion/duplication analysis for all four genes by array-CGH or MLPA.

In the 1990's, gene testing was mostly done a research-based activity. After the Human Genome Project, companies started offering gene sequencing (Beginning of commercially availability for gene sequencing, Ambry Genetics, City of Hope, GeneDx, Mayo, Baylor, etc.). In the middle of 2000, Sanger sequencing for individual genes or a small group of related genes were offered. Mini-sequencing technologies emerged and let the promise of a more flexible platform to add new mutations or genes to the sequencing chip. However, the cost remains high and to lower the cost, pooling sample became the only feasible way to offer gene testing panel [23]. This reality caused was problematic to small diagnostic laboratories and more importantly for rare orphan diseases.

In the late 2000's, next-generation sequencing started to be used for sequencing medium and large gene panels. These sequencing technologies have benefits (faster diagnosis, reduced costs) and limitations (do not include all genes, incidental findings, variant of unknown significance). In an universal health care system, like in Quebec, diagnostic utility and yields are as important as cost efficiency. Current panels in use are a brief glimpse into the future of molecular diagnostic. Variants of unknown significance will continue to decrease over time and the next generation sequencing will perform better for the detection of copy number and complex rearrangements.

2.3. The “Omic” Approach, a Comprehensive Interrogation

The introduction of massively parallel sequencing platforms impacted on the cost of sequencing which in turn created, together with progresses in bioinformatics tools, a novel era of study in life sciences. These studies focus on large-scale data and can be divided into three main categories: genomics, proteomics and metabolomics hence the term “omic”. Thanks to this technological growth there came new clinical opportunities. These include: identification of genetic mechanism of heterogeneous disorders (those with dozen and hundreds of genes involved), targeted therapy (especially in cancer), targeted treatment (pharmacogenomics), prenatal screening (example, detection of Trisomy 21 through circulating cell free fetal DNA) and population screening for disease risk.

Genetic variations are a significant determinant of health and response to healthcare. Indeed, 70% of medical decisions rely on clinical laboratory results, and genetic innovations

will be a major source of diagnostic and prognostic information in this century. Although the number of genes linked to diseases is continually growing, the number of diagnostic tests has unfortunately lagged behind. Furthermore, complex diseases are expected to be caused by rare variations in a large number of functionally linked genes. For example, non-syndromic intellectual disability (NSID), the most frequent form of intellectual disability representing up to 2/3 of all cases, is caused by mutations in at least 34 genes. Together, these still explain less than 10% of sporadic intellectual disability cases, suggesting that the total number of NSID genes is likely to be above 100. Other well-documented examples of diseases showing high genetic heterogeneity include the spinocerebellar ataxias (35 genes), cardiomyopathies (150 genes), retinitis pigmentosa (78 genes), and deafness (160 genes). Comprehensive gene screening assays for each of these diseases is beyond the capabilities of the majority of diagnostic laboratories. The “omics” era holds the potential to solve the current problem of expanding molecular diagnosis by sequencing at once all the genes in the patient. Exome and genome sequencing are becoming cost-effective in a clinical setting as proven by the multiplication of providers offering clinical exome sequencing in the help for diagnosis (ex: Baylor College of Medicine, Ambry Genetics, GeneDx, UMC St Radboud, etc.).

Establishing an accurate diagnosis is the keystone on which medicine is based. However, an accurate diagnosis can only be accomplished through the use of diagnostic tools that are thoroughly validated for many properties (analytical validity, clinical validity, clinical utility, cost/effectiveness and cost-utility) and supported by the appropriate evidence-based data. A definitive diagnosis greatly facilitates the genetic counseling of families with diseases of early onset, leads to timely intervention, improved outcomes, and provides great reassurance to individuals and their families that they suffer from a known and definable disease.

Sequencing the exome of a patient in a clinical basis is of great value in two obvious situations: 1) finding a new mutation in a known gene underlying an “atypical presentation” (many examples can be found in the FORGE project, *Finding of Rare Disease Genes*: <http://www.cpgdsconsortium.com/>) and 2) identifying mutations in a novel gene. This could only be possible through a comprehensive approach. Moreover, exome sequencing is a faster and cheaper diagnostic method, it decreases the use of tests and additional consultations, is more accurate and offers personalized treatment. For example, a disease (intellectual disabilities) caused by mutations in ~100 genes will require sequencing of each gene, one at a time, at a cost ~ \$ 1,000/gene, and will take several years, for a total cost of over 100,000\$. With exome sequencing, screening of these 100 genes now costs ~\$ 2,000-\$ 7,000 (this cost and analysis turn-around time will decrease rapidly over the next few years). An “omic” approach can also have a positive economic impact. As an example, a 7 year old patient who presented with a neurodegenerative clinical picture characterized by spasticity was referred for exome sequencing. Prior to the sequencing of its entire genes, three pediatric neurologists assessed the child and a plethora of clinical examinations, biochemical tests and medical tests were completed. The three neurologist offered different diagnoses such as spastic paraparesis (> 45 known genes), spinocerebellar ataxia (> 15 known genes) and mitochondrial disease (> 300 known genes). The exploration of these assumptions was simply prohibitive as proposed by the clinical genetic testing targeted 20 genes and would have cost > \$ 40,000. Exome sequencing, with a cost of ~\$ 7000 rapidly led to the causative mutation/gene.

The major hurdle of exome sequencing is the missing or suboptimal exons coverage mainly due to high GC content. One good example is the aortopathies characterized by aortic dilation, which can lead to life threatening aneurysms and/or dissections. An early diagnosis is critical,

since timely initiation of pharmacological treatment can slow dilation and prophylactic surgery can prevent aortic dissection or rupture. Mortality rate is 20% for aortic dissections. Mutations in twelve different genes (for a total of 360 exons) are known to be responsible for these diseases. The commercial kit of exome capture SureSelect from Agilent is missing (or suboptimal) 11% exons of these genes. Fortunately, these weaknesses will be overcome with promised technological update.

3. THE FUTURE OF MOLECULAR DIAGNOSTIC LAB: WHAT WILL BE KEPT AND WHAT WILL BE DROPPED

Routine DNA-based diagnostic sequencing for neurodevelopmental or metabolic disorders currently targets well-defined genes or sets of genes that address very specific clinical questions. Today, available services vary greatly depending on the diagnostic laboratory, including Sanger sequencing of complete genes harboring mutations with known, well-described clinical phenotypes or multi-gene testing panels or next-generation sequencing-based disease/phenotype panels. Test ordering depends on the ability of a physician to apply a differential diagnosis; it follows a paradigm where a patient with phenotype A will have a mutation in a known gene causing phenotype A, which will be sequenced. Today's reality is that several genes are known to cause almost any particular phenotype, so gene panels can be used to sequence multiple genes simultaneously, or in a linear approach where the most commonly mutated genes are sequenced first, and if a negative result is obtained, the remainder are sequenced. The recent advances of next-generation sequencing enable the laboratory to simultaneously sequence a large number of genes at a significantly decreasing cost per gene. This raises multiple questions - is there a point at which additional sequencing diminishes the clinical utility of the resulting data? Is the proliferation of DNA testing panels enabled by next-generation sequencing beneficial for clinical diagnostics? What will be kept and what will be dropped?

This type of linear strategy is generally very satisfying for the diagnosing clinician as each test in specific population, for example in micro founder effect of Cree subpopulation or Saguenay, has a known value for diagnostic purpose. It also utilizes a focused approach, which tends to prioritize the most common gene involved in a certain phenotype. The genetics field is still young, but the actual genes and associated casual mutations are often incrementally discovered. Newly discovered genes are reported weekly, but it is generally difficult to systematically add them to a laboratory test menu. The diagnostic value from a single, well-characterized gene is relatively high since it is easier to interpret and it minimizes the likelihood that a variant of unknown significance will be discovered [64]. However, if a gene is reported only for a few cases, the diagnostic test may not be offered. Offering genetic testing for rare orphan disease has a high relative cost of test development and a low diagnostic yield [41, 63, 64].

As described in the previous section, some specific mutation panels will remain for at-risk population until the cost of next-generation sequencing decreases further. In addition, triplet-repeat diseases because of the unstable dynamic nature of those mutations will continue to require the use of a multimodal approach.

Next-generation sequencing is really moving the field of towards comprehensive gene panels. Expanded comprehensive diagnostic gene panels have several advantages. First of all, the design of an expanded diagnostic panel is quite straightforward and begins by identifying all of the genes involved in the disease(s) being targeted. Adding genes to the list is simple and does not require additional cost, unless enrichment is needed [63]. More comprehensive gene panel tests will simplify test ordering by consolidating all candidate genes into a single diagnostic test. By taking a more comprehensive approach, the sensitivity of the test increases and the rate of molecular under diagnosis decreases by including genes with low-frequency. It will also allow the identification of the causative gene in patients with an atypical phenotypic presentation. Moreover, with the advent of next-generation sequencing, an expanded neurodevelopmental and metabolic molecular diagnostic sequencing panel becomes economically feasible, allowing diagnosis of extremely rare orphan disease in one genetic test.

Next-generation sequencing introduces some interpretative challenges which are not new to diagnostic testing, but the scale of incidental findings or number of variants of unknown significance will be far greater than any previous test. Sanger sequencing typically identifies three categories of mutations: known non-pathogenic or benign polymorphisms; known pathogenic mutations; and variants of unknown significance. Variants identified as known pathogenic mutations are straightforward to interpret as in most cases, there are clearly indicated for clinical action [76]. With time, and better variant databases, the experience gained using next-generation sequencing testing panels will provide more data to improve variant interpretation and, over time, reduce the total number of variants of unknown significance encountered during next-generation sequencing diagnostic test [76]. The molecular clinical approach should focus on immediate clinical benefit of next-generation sequencing, such as the ability to offer comprehensive gene panels, to provide a first-pass diagnostic yield, and to limit gene list to genes of known diagnostic value [64]. This will aid the interpretation of the data set in a way that the healthcare provider will be able to understand and utilize.

4. THE NON-TARGETED GENETIC STRATEGY GENERATES NEW ETHICAL CHALLENGES

Particular emphasis has been placed in recent years on the identification of rare disease genes due to the availability of new genomic sequencing technologies. As seen earlier, these technologies greatly facilitate the search for causative disease mutations since they allow the analysis of the 22,333 genes at once in a short period of time for a reasonable cost. As a result, more genetic mechanisms involved in rare diseases are known, and a portion of these findings are already translated into diagnostic tools. Indeed, the clinical sequencing (referring to exome or genome sequencing) is rapidly being integrated into the practice of medicine. Although technically feasible and proven to be successful [77, 78], several challenges remain surrounding the use of clinical sequencing. Nonetheless molecular diagnosis using genomic and genetic methods such as microarray CGH, exome and genome sequencing have in common several ethical, legal and social concerns with other methods of medical investigation. Because of the unprecedentedly large amount of information generated by these comprehensive tests on an individual, the concerns (e.g., content of the consent form), incidental findings, returning results to the patient, etc. are amplified.

4.1. Consent Form

Consent forms need to be adapted to the new generation of sequencing clinical test. The main addition to the current medical consent form is the extent to which the patients would have control/access to the whole data (exome/genome), what results might be returned to the patient and what are the potential risks. The consent form should also inform the patient about the possible risk of discovering unwanted findings (unrelated to the original medical investigation). For instance, the exome analysis may reveal that the patient is likely to get a serious and untreatable disease.

4.2. Data Storage and Sharing

Next-generation sequencing technologies generate terabytes of data, and storing this amount of data will constitute a challenge in itself but also raised ethical issues. The genetic information of individual genome that is derived from the clinical sequencing is an accessible and robust “login” into a patient identity. It can give information on the patient’s relatives, ethnic groups, and more. The Wellcome Trust and the National Institute of Health, two respective Institutions whose mission is to operate open access genetic and genomic databases for the benefits of researchers and patients, now restricted and controlled their web database access. They even formed specific committees to oversee the circulation of the data included in their databases. This was effective following the conclusion from the study of Homer and colleagues in 2008 demonstrating that genome-wide association derived data is sufficient to re-identify an individual that have participated in a study [79]. They concluded that anonymizing data was unsatisfactory to protect the confidentiality of research participants. Because the understanding, diagnosed and treatment of complex diseases such as cancer or pediatric disorders required comparison of genetic information from several hundreds and often thousands of individuals, genetic data sharing is critical for research and molecular diagnosis. To further illustrate the significance of protecting information derived from whole genome sequencing of individual, the Presidential Commission for the Study of Bioethical Issues published a 150-page report, on the Privacy and progress in the era of whole genome sequencing. They concluded *“to realize the enormous promise that whole genome sequencing holds for advancing clinical care and the greater public good, individual interests in privacy must be respected and secured. As the scientific community works to bring the cost of whole genome sequencing down from millions per test to less than the cost of many standard diagnostic tests today, the Commission recognizes that whole genome sequencing and its increased use in research and the clinic could yield major advances in health care. However it could also raise ethical dilemmas. The Commission offers a dozen timely proactive recommendations that will help craft policies that are flexible enough to ensure progress and responsive enough to protect privacy.”* Finally, researchers and policy-makers need to find methods to protect individuals’ genomic data while still being able to share information.

4.3. Incidental Findings

As mentioned in earlier sections, clinical exome and genome sequencing present several advantages for clinical practice and for the patient. The main advantage discussed is the nondiscrimination on the selection of candidate's genes that will be analyzed. However, these methods can yield incidental medical information not related to the principal medical target. For instance, the genome of a child investigated for a rare form of deafness can lead to the discovery of a known mutation leading to a late onset neurodegenerative disorder. In addition, the patient can be found to be carrier of a recessive lethal disease. These "secondary" findings have been the subject of many discussions and recently the American College of Medical Genetics and Genomics whose mission is to improve health through medical genetics released its highly anticipated "Recommendations on Incidental Findings in Clinical Exome and Genome Sequencing".

In addition to fortuitous findings, whole genome sequencing raises great social concerns that still need to be resolved, such as possible forms of discrimination. Efforts have been made to overcome this phenomenon since the Genetic Information Nondiscrimination Act was signed in the USA in 2008 to protect individuals from improper use of genetics information with regard to health insurance and employment [69]. Emerging discoveries of susceptibility genes and gene variants associated with major neurological or psychiatric disorders are likely to challenge the existing ethical guidelines. It is up to researchers, health professionals and experts in the Ethical, Economic, Environmental, Legal, and Social aspects of genomics [GE3LS] to manage this growing scientific knowledge in a way that prioritizes protection of research participants and improves patient care.

CONCLUSION AND FUTURE

The successful use of whole-genome and exome sequencing for diagnosis has been amply confirmed by numerous studies. Whether targeted gene, gene panel approaches and exome sequencing will be entirely replaced by whole-genome sequencing is still unknown. Compared to traditional methods, it is now well accepted that exome sequencing has fewer false positives, and a greater sensitivity due to the higher coverage achieved when focusing only on a small fraction of the genome. Exome and whole-genome sequencing allow the discovery of point mutations and small deletion. With advanced bioinformatics tool it is now feasible to detect larger insertions and deletions (CNVs), currently detected using the microarrays technologies. We think that these "cytogenetic" methods, including karyotyping and molecular diagnosis, will merge. We also think that the current modalities of next-generation sequencing will eventually be replaced by genome sequencing. Recently, Saunders and colleague showed the feasibility of using whole-genome sequencing in neonatal intensive care units to screen for genetic disease diagnosis [77]. They described a 50-hour delay in the diagnosis of genetic disorders using whole genome sequencing.

Some challenges will subsist: mosaicism, balanced translocation and complex diseases (unknown mode of transmission). However, an important challenge in using whole-genome sequencing will be the interpretation of the data linking a genetic variation to the disease/phenotype and all ethical issues around it.

The rapid development of sequencing is now positively impacting prenatal diagnosis. Since the discovery of cell-free fetal nucleic acids circulating in the blood of pregnant women, [80] combined with next-generation DNA sequencing technologies, it is now possible to do early, noninvasive prenatal genetic testing [81]. Clinical applications of these methods already include fetal sex determination and blood group typing [82]. Ongoing research is currently evaluating the use of this approach for noninvasive detection of trisomies [83]. Other uses being explored are the detection of single-gene disorders, chromosomal abnormalities and inheritance of parental polymorphisms across the whole fetal genome.

Use of preimplantation genetic diagnosis and preimplantation genetic screening using next-generation sequencing can provide blastocyst preimplantation genetic diagnosis (PGD) results with high level of consistency with established diagnostic methods. Furthermore, single-gene disorder screening by next-generation sequencing could be performed in parallel with qPCR-based comprehensive chromosome screening or array SNP-CGH. Several studies showed that next-generation sequencing could serve as an essential PGD tools for further development of this important and emerging field [84]. Next-generation sequencing data provides a unique opportunity to evaluate multiple genomic loci and multiple samples on one experiment (e.g foetus can be tested in parallel with the parents). Next-generation sequencing might also be useful for simultaneous evaluation of aneuploidy, single-gene disorders, and translocations from the same biopsy without the need for multiple technological platforms [85]. Clearly, the fertility field has seen intensive efforts to significantly improve and validate better state-of-the-art in vitro fecundation techniques. Martin J. et al. suggested that IVF techniques coupled with deep comprehensive diagnosis/screening methods using NGS should result in high implantation and live birth rates [85]. Nevertheless, there is always room for improvements; it is important to be prudent, recognize the limits of sequence depth necessary to maintain accuracy, and variation in sequencing depth across different genomic loci that is critical to its clinical application in PGD.

We expect that whole-genome sequencing will allow the identification of genetic variants that will determine an individual's risk for developing diseases, including neurological or psychiatric disorders. In fact, the continuing reduction in sequencing costs may lead to replacement of most of the other currently used approaches.

ACKNOWLEDGMENTS

We are very grateful for the support of our Institution. We wish to thank our colleagues, Mélanie Lafleur, Françoise Couture, Sylvie Filiatrault, Josée Gauthier, Janique Ladouceur, Caroline Deschaînes, Marie-Josée Lassonde, Julie Ménard, Li Fan and Marie-Lyne Darveau for their technical and administrative work in the Molecular Diagnostic Lab. We also acknowledge the work/input of our collaborative clinicians: Drs. Jacques Michaud, Grant Mitchell, Jean-François Soucy, Dorothée Dal Soglio, Luc Oligny, George-Etienne Rivard and Sonia Cellot for their help in the discovery, development and for working in close collaboration to improve the use of genetics and genomic knowledge and tools in today's medicine.

ABSTRACT

Viral vectors engineered to carry transgenic sequences can be delivered into discrete tissues or anatomical structures to express specific transgenes into the transduced cells. Therefore, they are useful tools to produce specific, transient and localized knockout, knockdown, ectopic expression or overexpression of a gene, leading to the possibility of analyzing both *in vitro* and *in vivo* molecular basis of relevant functions. Replication-incompetent helper-dependent amplicon vectors, derived from herpes simplex virus type-

1 (HSV-1) are devoid of viral genes. Thus, these vectors have great advantages as tools for *in vitro* and *in vivo* gene transfer and, in particular (i) minimal toxicity or induction of adaptive immune responses, and (ii) large transgene capacity, being able to carry up to 150 kbp of foreign DNA. In addition, these vectors have (iii) widespread cellular tropism: amplicons can experimentally infect several cell types, either quiescent or not, though naturally HSV-1 infects mainly neurons and epithelial cells, and (iv) absence of insertional mutagenesis, since the viral genome does not integrate into the host cell genome. These vectors have been used both on basic and applied research, and they have revealed as most suitable tools to study complex functions involving the nervous system, such as anxiety, sexual behavior, learning and memory. In addition, amplicon vectors are being used for the development of new experimental gene therapy approaches, both for inherited and acquired diseases affecting the nervous system, including neuro-degenerative diseases. Although several technological improvements have been achieved in the last decade, some difficulties regarding these appealing vectors remain still unresolved, such as the inability to generate large amounts of high-titer fully helper-free vectors and the fact that expression from the transgenic sequence delivered by the vectors is generally unstable, often leading to a complete silencing of expression after a few weeks. To overcome these obstacles and to improve these vectors, we have recently modified (a) the amplicon genome, in order to fully delete bacterial sequences and (b) developed novel complementing cell lines, in order to improve helper-free vector production and to render amplicon stocks compatible with clinical trials. In this review article we briefly review data supporting the potential of HSV-1-based amplicon vector model for gene delivery in primary cultures of neural cells and into the brain of living animals.

Keywords: HSV-1-derived vectors, Amplicons, nervous system, neurodegenerative disorders, cancer, vaccines, experimental gene therapy

HSV-1 BACKGROUND

HSV-1 Epidemiology and Clinical Features

HSV-1 is one of the most common human pathogens, infecting 40–80% of people worldwide. Primary, productive infections of HSV-1 typically occur in regions of the orofacial mucosa, causing a mild gingivo-stomatitis. The virus particles produced during this primary infection enter the peripheral sensory neurons, where the virus genome often remains into a latent for the lifetime of the host. Reactivation, occurring generally following stress, usually leads to recurrent lesions in the vicinity of the primary infected area and are typically limited to cold sores of the mouth. Although recrudescence herpes may affect any site along the involved sensory division of the fifth cranial nerve, the most frequent location is the muco-cutaneous junction of the lips [1]. Classic lesions are characterized by virally induced epithelial damage and go through different clinical stages. Initially, a transient cluster of micro-vesicles appears at the site of recrudescence and breaks open to form irregular, superficial erosions that crust over and heal without scarring over a period of 1–2 weeks. Shedding of the virus is often present for several days after resolution of clinical signs and symptoms [1]. HSV-1 infection can also cause ocular herpes and, much more infrequently, it can cause encephalitis. In neonates and in immune-depressed individuals HSV-1 can cause severe disseminated infection with neurological impairment and high mortality [2].

HSV-1 Virion Structure

The architecture of this enveloped double-stranded DNA virus, of 220 nm in diameter, is highly complex [3]. The mature HSV-1 virion (Fig. 1) consists of the following four components:

- A core of double-stranded (ds) DNA
- An icosadeltahedral capsid
- The tegument, which is a layer of proteins located between the envelope and the underlying capsid; these proteins play a critical role in virion morphogenesis, and they also help the virus to take the control of the expression machinery of the cell very early following infection
- A lipid envelope from cellular origin, where viral glycoproteins and other membrane proteins are embedded, several of which are involved in receptor-mediated cellular entry.

Figure 1. HSV-1 Virion.

HSV-1 Genome

The linear 152-kbp dsDNA virus genome (Fig. 2) is densely packaged within the capsid cavity [4] and is devoid of histone proteins at this stage [5]. This genome is arranged as long (UL) and short (US) unique segments, of 126 and 26 kbp, respectively. The UL and US segments are flanked by repeated sequences, designated ab, b'a' a'c' and ca (or TRL, IRL, IRS and TRS, for Terminal Repeat L, Internal Repeat L, Internal Repeat S and Terminal repeat S) [6].

The HSV-1 genome, which is 68% G+C rich, has been fully sequenced [7-9]. At least eighty-four viral genes are encoded, and these may be divided into essential and non-essential genes, according to whether their expression is necessary or not for viral growth in permissive cultured cells. HSV-1 genes do not contain intron sequences, with the exception of those encoding ICP0, ICP22, ICP47, UL15 and LAT. Nonessential genes often encode functions that

are important for specific virus-host interaction *in vivo*, such as immune evasion, replication in non-dividing cells or shutdown of host protein synthesis. Approximately half of the viral genes have been shown to be dispensable for replication of the virus in cultured cells, and thus, these genes could be replaced by exogenous genetic material, which has been the premise for the development of HSV-1-based vectors for gene therapy [10]. In contrast, most genes involved in virus entry, DNA replication, capsid assembly and DNA packaging are essential.

Figure 2. HSV-1 genome.

The HSV-1 genome contains two *cis*-acting sequences that are essential for virus multiplication: the viral DNA replication origins and the cleavage/packaging signals. HSV-1 harbors three lytic origins of replication, with two located within the repeated segments surrounding US (oriS) and one in the UL segment (oriL) [11]. Mutant viruses lacking either oriL or both copies of oriS are replication competent, suggesting that all origins are functionally competent [6]. The oriS is located within the shared promoter regulatory region between the divergently transcribed immediate-early genes ICP4 and ICP22/ICP47, whereas oriL lies in the regulatory region between two divergently transcribed early genes that are essential for viral DNA replication: the major DNA-binding protein and the HSV-1 DNA polymerase [12].

The cleavage/packaging signals of the HSV-1 genome are located within the *a* sequences, generally found in tandem repeats at both ends of the genome, as well as at the L/S junction [13, 14]. In different HSV-1 strains, the *a* sequence ranges from 250 to 500 bp. An approximately 200-bp fragment (Uc-DR1-Ub) spanning the junction between tandem *a* sequences has been shown to contain all the essential *cis*-acting sequences necessary for DNA cleavage and packaging [15]. The specific signals for DNA cleavage and packaging, termed pac1 and pac2, are located within the Ub and Uc regions, respectively [14-16].

HSV-1-DERIVED VECTORS

The improvement of methods for efficient delivery of genetic material in mammalian cells has been a major objective of molecular and cellular biology, gene therapy and vaccine development during the last 30 years and is still a subject of increasing interest. Viral-derived

vectors are the most promising gene transfer tools as viruses have naturally evolved as molecular carriers to specific tissues. As already quoted, HSV-1 is a naturally epithelial-neurotropic virus, highly adapted to the nervous system environment of the host organism, and neurons and glia are thus the most common target cells for HSV-1-derived vectors. Coding more than 80 genes, HSV-1 is a complex virus, which can be engineered to exquisitely design viral vectors for fundamental research and gene therapy of neurological disorders. In general terms, HSV-1 possesses several features that make it especially interesting as a vector:

- Although essentially neurotropic, under experimental conditions HSV-1 has a broad host cell range, due to the fact that its cellular receptors are widely distributed. In addition, HSV-1 infects and replicates in cells from different mammals, easily allowing preclinical evaluation.
- It can infect dividing and non-dividing cells.
- It generally causes nonthreatening diseases.
- It has a very large transgene capacity, allowing to deliver multiple or large transgenes (approximately half of the genome is nonessential in cultured cells and can be deleted without compromising viral replication, allowing to lodge considerable amounts of transgenic DNA). Moreover, HSV-1-derived amplicon vectors are devoid of almost the totality of their genome (i.e., 152-kbp DNA), which can therefore be replaced by exogenous DNA.
- Safe replication-defective HSV-1 vectors may be prepared to high titers.
- The ability to establish a latent state in neurons may be very useful for stable long-term expression of therapeutic transgenes.
- HSV-1 genome does not integrate into host chromosomes, remaining episomal and reducing the risk of insertional mutagenesis.

To exploit the versatility of HSV-1 for gene transfer, three types of HSV-1-based vectors have been developed: **(i)** attenuated replication-competent vectors, **(ii)** replication-defective recombinant vectors, and **(iii)** amplicon vectors. Attenuated replication-competent HSV-1 vectors can replicate only in certain cell types and tissues *in vivo* due to deletion of non-essential viral genes. Such vectors have been typically used for the development of tumor therapies, and are usually referred to as oncolytic HSV-1 vectors. However, other uses of attenuated vectors are possible, for example to deliver genes to the peripheral sensory ganglia following infection at peripheral tissues. Replication-defective recombinant HSV-1 vectors are devoid of one or more viral genes that are essential for lytic replication (such as the immediate early genes ICP4 and ICP27), but they can retain their ability to establish latency [17, 18]. The production of these vectors requires complementing cell lines expressing the deleted viral genes. This type of vectors can be used as genetic vaccines or for gene therapy of neurological disorders.

Lastly, Spaete and Frenkel [19] reported the natural generation of fully defective HSV-1 genomes, in which almost all the transacting virus genes were absent. These defective genomes were formed mainly by repeats of the two non-coding HSV-1 sequences, i.e., the origins of DNA replication and the cleavage/packaging signals. Moreover, they have showed that these defective genomes could be replicated and packaged into particles in the presence of a helper virus that supplied all the virus functions *in trans*, thus demonstrating that the origins of virus replication and the cleavage/packaging signals were the only two *cis*-acting sequences required for replication and packaging of a defective virus genome. These *cis*-acting sequences from the

HSV-1 genome were then incorporated into a standard bacterial plasmid, which they have termed the amplicon plasmid [19], and they demonstrated that the amplicon plasmid could also be replicated and packaged into viral particles in the presence of a helper system, thus generating what they have termed amplicon vectors. This chapter will be devoted to the biology and applications of this very appealing type of vectors.

Amplicon Vectors

A conventional HSV-1 amplicon plasmid consists of (i) a plasmid backbone harboring a bacterial origin of DNA replication and an antibiotic resistance gene for propagation in bacteria, (ii) an HSV-1 origin of DNA replication (generally oriS), (iii) an HSV-1 cleavage/packaging sequence (pac or *a*), (iv) a transcription unit expressing a reporter gene, generally encoding the green fluorescence protein (GFP), which is useful for identifying the amplicon-infected cells and to facilitate the titration of amplicon stocks, and (v), a multiple cloning site (MCS) for introducing the transgene(s) of interest (Fig. 3). This basic structure of amplicon plasmids has remained almost unchanged from the beginning [19].

Figure 3. Structure of a typical amplicon plasmid.

Heterologous transcription units, either alone or in combination, can be cloned into amplicon plasmids using conventional molecular cloning techniques; the resulting construct is then packaged into viral particles to be then used for transduction of cells or tissues. From the structural point of view, amplicon vectors are virus particles structurally and immunological identical to wild-type HSV-1 particles, but bearing, instead of the virus genome, a concatemeric form of DNA amplified in a head-to-tail arrangement, which derives from the amplicon plasmid (Fig. 4).

Amplicon vectors have been used both on basic and applied research, and they have revealed as most suitable tools to study complex functions involving the nervous system, such as anxiety, sexual behaviour, learning and memory. In addition, amplicon vectors are being used for the development of new experimental gene therapy approaches (both for inherited and acquired diseases affecting the nervous system, including neurodegenerative diseases) [20-23],

vaccine development [24, 25], hybrid viral vectors (such as adeno-associated and lentivirus viruses) [26, 27], human artificial chromosome technologies [28, 29] and basic research. It is not possible to fully describe these applications in the short extent of this manuscript. For a more detailed description of amplicon vector applications, please refer to Cuchet *et al.* (2007) [30], Epstein (2009) [31], Fraefel (2007) [32], Manservigi *et al.* (2011) [33] and de Silva and Bowers (2009) [10].

Figure 4. Concatemeric amplicon DNA replication.

Amplicon Vector Properties

The amplicon system has several properties that make it a reliable and efficient method for gene transfer.

1. The two HSV-1 elements required to support replication and packaging into virions, i.e., the *oriS* and *a* sequences, are smaller than 1-kbp. Since the HSV-1 particle can package up to 153-kbp, this means that the amplicon particle has the potential to accommodate very large fragments of foreign DNA, including multiple and/or large transgenes or large cell type-specific regulatory sequences. This is the most remarkable feature of amplicon vectors, as there is no other available viral vector system displaying the capacity to deliver such a large amount of foreign DNA (~150-kbp) to the nuclear environment of mammalian cells.
2. Depending on the size of the amplicon plasmid, several copies of the transgene can be packaged into a single vector particle [34], thereby increasing the transgene dose per infected cell. This happens because the amplicon genome is replicated via a mono-directional rolling circle-like mechanism, therefore generating long concatemers composed of tandem repeats of the amplicon plasmid, and because each HSV-1 amplicon particle always cleaves and packages a ~150-kbp DNA molecule, which represents the HSV-1 particle packaging capacity [35].

3. The HSV amplicon is not an 'alive' virus but an inert particle, bearing an inherently safe *in vivo* profile. Although amplicon genomes carry no virus genes and consequently do not induce synthesis of viral proteins, the approximately 40 different HSV-1 structural proteins that shape the HSV-1 virion (which are the same in the amplicon virion) are delivered into the cell during infection and can trigger cell signaling and cellular responses, probably having a transient impact on cell homeostasis and cellular gene expression. Nevertheless, these proteins soon disappear and the cells can resume their normal functions, including the ability to divide and to respond to physiological stimuli. Furthermore, the absence of viral genes in the amplicon genome strongly reduces the risk of reactivation, complementation or recombination with latent or resident HSV-1 genomes.
4. As already quoted, after primary HSV-1 infection of epithelial cells, the virus particles can enter sensory nerve endings and the capsid is moved via retrograde axonal transport to the neuronal cell bodies of the sensory ganglia, where the virus genome may establish a latent infection. Most of these mechanisms are certainly reproduced by amplicon vectors, since the mature amplicon particle is identical to that of the helper HSV-1 and they will thus behave as normal virion particles. However, it is not yet clear if the amplicon genome can establish a latency-like long-term expression in sensory neurons.
5. Once packaged into viral particles, the amplicon vector retains the ability to infect numerous cell types, and its genome is maintained in an episomal state within the nucleus of the infected cell. Due to the absence of viral gene expression, the amplicon is replication-defective, and its episomal existence results in stable maintenance in post-mitotic cells, but leads to unequal segregation in mitotically active cells. Since it does not integrate into the host cell genome, the conventional amplicon does not lead to insertional mutagenesis, thus increasing its safety profile as a gene therapy vector.

Amplicon Production Systems

Production of amplicon vectors involves the coordinated action of more than 50 viral proteins, required to allow replication and packaging of the amplicon plasmid into fully infectious virus particles. Amplicon plasmids are therefore dependent on helper HSV-1 virus proteins, and the genes encoding these proteins could in principle be supplied by a helper HSV-1, or by HSV-1 viral DNA.

The most important limitation for the use of amplicons in gene therapy trials is the difficulty to produce large, high-titer stocks of vector particles free of helper virus contamination. At present, there are two major methods used for producing amplicon vectors with low or even without HSV-1-helper-contamination (Fig. 5): one is based on transfection of the amplicon plasmid with HSV-1 helper genome (either as bacterial artificial chromosome (BAC) or as cosmid-based packaging systems), and the other, is based on transfection of the amplicon plasmid in cells expressing Cre recombinase, followed by infection using a defective helper HSV-1 carrying loxP sequences surrounding the packaging signals.

Helper DNA-Based Packaging Methods

DNA-based packaging methods for amplicon production are carried out by co-transfecting amplicon plasmids with HSV-1 genomes lacking their packaging signals. This system, initially derived from a set of five overlapping cosmids, each one carrying a large fragment of the virus

genome, which allows the reconstitution of a full virus genome by homologous recombination, in cells co-transfected with the full cosmid set [36]. By deleting the *a* sequences from the two cosmids carrying them, this system generates a virus genome that is able to express all the required transacting functions but which cannot itself be packaged into HSV-1 particles. The co-transfection of amplicon plasmids with the modified set of cosmids allows therefore the production amplicon vectors. Using this system, however, amplicons are produced in relative low amounts (10^5 - 10^6 TU/mL) [37], and the vector stocks can be barely contaminated with helper virus particles.

Figure 5. Amplicon production systems. (A) DNA-based packaging system: Vero ICP27-expressing cells are co-transfected with the amplicon plasmid, the fBACΔpac BAC (which carries a non-packageable HSV-1 genome) and an ICP27-expressing plasmid, and amplicon vectors are harvested from cells 2 or 3 days post-transfection. (B) Helper virus-based packaging system: Vero ICP4-expressing cells are transfected with an amplicon plasmid and super-infected with the HSV-1 LaLΔJ helper virus. At two days post-infection, the mixed population of viral particles (amplicons and helper particles) is used to infect ICP4/Cre recombinase-expressing cells. After 2 days, amplicon vectors, only barely contaminated with defective helper particles, are harvested from infected cells.

This approach was later simplified and significantly improved by cloning the entire HSV-1 genome, only devoid of *a* signals, into a bacterial artificial chromosome (BAC), thus generating a BAC-HSV-1 [38, 39]. In the last version of this system, the gene encoding the essential ICP27 protein was further deleted from the BAC-HSV-1 genome, which was then increased in size by adding non-coding DNA to further reduce the probability of being packed into newly assembled HSV-1 particles [39, 40]. The ICP27 protein is supplied *in trans*, both by a plasmid and by complementing cell lines expressing this protein (Fig. 5A). This system gave rise to the production of entirely helper-free amplicon stocks for the first time. Vector

titers obtained from helper virus-free amplicon packaging can range from 10^7 to 10^8 TU/ml, but the total amount of particles is somewhat limited by the fact that vector stocks produced in this way cannot be serially passaged.

Helper Virus-Based Packaging Methods

Historically, the first method to produce amplicon stocks was based in the transfection of cells with the amplicon plasmid, followed by super-infection with a helper HSV-1 virus, to supply *in trans* the necessary viral functions. One advantage of this system was that the vector/helper stock thus produced could be serially passaged, to produce as many amplicon particles as required. Although this method allows to produce large amounts of amplicon vectors, its major limitation is that it leads to a mixed population of particles, highly contaminated with HSV-1 helper particles, which induces strong cytotoxicity and immune responses upon infection of target cells or organisms, thus impeding their use in gene therapy and even in many fundamental studies. Due to the identical physical properties of both amplicon and HSV-1 helper virus particles, a selective purification of amplicon particles by physical treatment is not feasible.

Therefore, different strategies have been successively developed in order to reduce the toxicity of the helper-contaminated amplicon stocks, firstly by modifying the helper virus genome in order to limit its toxicity, and secondly, by limiting the production of contaminant particles. The first approach to improve this virus-based method was the use of a thermosensitive HSV-1 as helper [41]. Subsequently, defective helper HSV-1 viruses, carrying deletions in immediate early genes encoding one essential protein [42–45] were developed. However, and despite obtaining relatively high titers, these amplicon stocks were still contaminated with large amounts of defective HSV-1 helper particles, resulting in significant cytotoxicity and inflammation.

LaL and LaLΔJ HSV-1 Helper System

More recently, an attractive approach to produce amplicon vectors using the helper virus-based system, was developed to avoid or to limit helper genome packaging while producing high amounts of amplicon stocks. This system is based on the deletion of *a* sequences from the HSV-1 helper genomes by a Cre/loxP-based site-specific recombination, in order to abolish their packaging in the cells that are producing the amplicon vectors. The first of these helper systems, named HSV-1 *LaL* (for lox-*a*-lox) helper, carried a unique and ectopic *a* sequence flanked by two parallel loxP sites, located in the gC locus [46, 47]. This virus is therefore Cre-sensitive and cannot, in principle, be packaged in Cre-expressing cells due to deletion of the floxed *a* sequence. Nevertheless, some helper genomes could escape the action of the Cre recombinase, allowing the production of some helper particles, which are replication-competent and able to spread.

To further improve this helper system, the two genes surrounding the *a* sequence, encoding the virulence factor ICP34.5 and the essential protein ICP4, were deleted from the *LaL* genome, generating the *LaLΔJ* helper virus [48]. Although the amplicon stocks prepared with this helper, in a cell line trans-complementing both Cre and ICP4 proteins (Fig. 5B) still contain a very small amount of contaminating helper particles, the replication-incompetent *LaLΔJ* helper cannot spread upon infection of target cells or tissues. Use of the HSV-1 *LaLΔJ* helper virus generally results in the production of large stocks of amplicon vectors with titers often

exceeding 2×10^8 TU/mL, and only barely contaminated (about 1.0%) with defective, non-pathogenic helper particles. Nevertheless, the presence of contaminating helper virus, even at very low levels, could still be a limitation for the use of amplicon stocks in some gene therapy applications. Therefore, the approaches to produce amplicon vectors should still be improved in order to produce high amounts of high-titer of entirely non-toxic amplicon stocks.

Further Improvements of Amplicon Vectors Technology

Although several technological improvements for amplicon vectors production have been thus developed in the last decade, several difficulties remain still unresolved. These include: (i) cytopathic effects and immune responses induced by gene expression from potential helper virus contaminants; (ii) potential reversion of helper virus contaminants to the wild type HSV phenotype; (iii) potential interactions with residing HSV-1, eventually leading to complementation, reactivation and recombination; (iv) the inability of the vector genome to be maintained in proliferating cells; (v) the presence of bacterial DNA sequences, which can lead to inflammatory responses and to the silencing of transgene expression, and (vi) the already quoted inability to generate large amounts of high-titer vectors fully free of contaminant helper particles. To overcome some of these obstacles and to improve these vectors, we have recently introduced two modifications to the amplicon vector production system, corresponding to: (i) the amplicon genome, in order to fully delete bacterial sequences and (ii) the nature of the complementing cell lines where the amplicons are produced, in order to improve helper-free vector production. We briefly describe in the following paragraphs our ongoing program to improve the amplicon methodology.

Elimination of Bacterial DNA from the Amplicon Genome

It is known that the presence of bacterial sequences in transduced plasmids can induce silencing of the transgene cassette, as well as innate and inflammatory reactions. In addition, bacterial sequences are outlaw in gene therapy protocols. In the case of amplicons, it was recently demonstrated that the presence of bacterial sequences in the amplicon plasmid (and thus, also present in the amplicon vector genome) cause inflammatory responses and rapid transgene silencing, by forming inactive chromatin [49]. In this regard, it has been shown that infection with amplicon vectors lacking bacterial sequences (minicircle amplicon vectors) induced approximately 20-fold higher transgene expression due to transcriptional enhancement [49]. In addition, nude mice injected with minicircle amplicon vectors exhibited 10-fold higher luciferase expression than mice injected with conventional amplicons, detectable up to at least 28 days post-infection [49]. Elimination of these bacterial DNA sequences from the amplicon genome is therefore critical if the vectors will be used in gene therapy.

Our efforts to eliminate bacterial DNA from the amplicon genome are based on the modification of the amplicon plasmid. We have recently generated a new amplicon plasmid, named pOPNE (Fig. 6), which possesses a typical plasmidic backbone with a bacterial origin of DNA replication (*E. coli* ori) and an antibiotic resistance gene (AmpR). This plasmid also contains an amplicon cassette surrounded by two loxP (L) sites in parallel orientation. As usual, the amplicon cassette carries one HSV-1 oriS and one pac (or *a*) signal. Note that the oriS sequence is linked to the HSV-1 IE4/5 promoter (IE4/5), very close to one of the loxP sites. pOPNE also contains a Neomycin/Kanamycin resistance gene (Neo) bordered by two FRT sites (F). This FRT-bordered cassette will serve as an acceptor locus for the introduction of transgenes through FRT-flipase site-specific recombination. Finally, the amplicon cassette also

possesses a promoterless EGFP (enhanced-GFP) reporter gene, juxtaposed to the second loxP site.

Preliminary results (not shown here), indicate that when the pOPNE plasmid is transfected in Cre recombinase-expressing cell lines, the amplicon plasmid recombines at the loxP sites, thereby producing two molecules: one minicircle carrying the bacterial sequences present in the plasmid backbone (residual DNA) and a second minicircle carrying the complete amplicon module devoid of bacterial sequences (Fig. 7). In addition, the Cre recombinase-mediated deletion of the bacterial sequences brought the IE4/5 promoter upstream the promoterless-EGFP open reading frame (ORF), therefore leading to EGFP transcription. Following infection of these cells with helper HSV-1, the amplicon genome was then encapsidated into HSV-1 particles. These particles expressed EGFP upon infecting target cells, therefore demonstrating that they have lost the bacterial sequences between the promoter and the EGFP ORF. These vectors are therefore appropriate for further used in gene transfer approaches. We are currently investigating the biological properties of these bacterial DNA-free amplicon vectors.

Figure 6. Structure of pOPNE amplicon plasmid. *ori*: bacterial origin of DNA replication; *AmpR*: Ampicillin resistance gene; *L*: loxP sites; *oriS*: HSV-1 origin of DNA replication; *pac*: HSV-1 cleavage/packaging-encapsidation sequence; *IE4/5*: HSV-1 IE4/5 promoter; *F_Neo_F*: Neomycin resistance gene bordered by two FRT sites (F); and *EGFP*: EGFP reporter gene, without promoter.

Figure 7. Cre recombinase-mediated cleavage and dissociation of pOPNE plasmid. Upon Cre recombinase expression, the amplicon plasmid pOPNE is dissociated into two DNA molecules: one carries the residual bacterial DNA and another carries the amplicon sequences devoid of bacterial DNA.

Modification of the Complementing Cell Lines

VCre4 Cell Line

As already quoted, when using HSV-1 *LaLΔJ* as helper virus, the helper particles are eliminated through a Cre/loxP-based site-specific recombination event that requires thus the expression of Cre-recombinase in the infected cells, in addition to the expression of the essential protein ICP4, whose gene is absent in this helper system. Previous cell lines expressing simultaneously ICP4 and Cre recombinase, that were used for the production of amplicon stocks with HSV-1 *LaLΔJ* helper, were derived from TE-671 cells (human rhabdomyosarcoma cells, ATCC CRL 8805) [46]. As these cells are cancer-derived cell lines, they cannot be used to produce vectors for gene therapy. In contrast, Vero and Vero-derived cell lines are approved for gene therapy approaches by the Food and Drug Administration (FDA - U.S. Department of Health and Human Services) [50].

Therefore, we have recently constructed another cell line, derived from Vero cells, which we named VCre4. These cells express Cre recombinase under the control of the HCMV promoter and the ~10.4-kbp ICP4 locus including its own promoter (HSV-1 bases 126,764-131,731). Preliminary results have shown that VCre4 cells produce higher levels of amplicon vector stocks than the previous system and these stocks contains lower than 1% of contaminant defective helper particles (data not shown here). Therefore, not only VCre4 cells provide a better packaging cell system but, in addition, the creation of this novel Vero-based cell line, brings amplicon vector technology closer to gene therapy protocols and represents a promising approach to treat neurodegenerative diseases.

AMPLICON VECTORS AND CANCER

In this section we present a very brief summary about some past and recent applications of HSV-1 derived vectors to cancer research and experimental therapy.

HSV-1-amplicon vectors have been tested for treatment of different experimental tumours, both in brain and in other organs and tissues, exploiting its inherent absence of toxicity and ability to infect many different cell types. Since these vectors can efficiently deliver transgenes to cancer cells, but they are diluted during successive cell divisions, most studies have used acute approaches by delivering pro-drug activating enzymes, cytotoxic proteins, apoptosis-inducing factors, fusogenic proteins and small interfering RNAs (siRNAs) for growth factor receptors. In addition, several studies have targeted amplicon vector entry or expression in order to improve treatment efficacy and selectivity.

Targeting tumour cells using HSV-1 vectors is a complicated issue as the process involves multiple interactions of viral envelope glycoproteins and cellular host surface proteins. In order to improve the selectivity of amplicon vectors tropism for tumour cells, such as glioma cells, the heparan sulfate-binding domain of glycoprotein C (gC) has been replaced with a human glioma-specific peptide sequence (MG11). Preferential homing of these virions in glioma cells was confirmed in a xenograft glioma mouse model, following intravascular delivery [51]. Another important issue is the inefficient distribution of vector particles *in vivo*, which may limit their therapeutic potential in patients with gliomas and, in this context, it has been recently

demonstrated that vector-mediated gene expression in gliomas was strongly dependent on vector application-injection pressure and injection time [52].

In order to improve efficiency and safety of cancer gene therapies, efforts have been made at specifically targeting proliferating cells in glioma models. The HSV-1 immediate-early gene ICP0 possesses E3-ubiquitin ligase activity [53] and it can induce the degradation of centromeric proteins [54]. Amplicons expressing the HSV-1 ICP0 were used to infect human glioblastoma Gli36 cells and well-established models of non-dividing cells, such as primary cultures of either rat cardiomyocytes or brain cells. ICP0 induced a strong cytostatic effect and significant cell death in Gli36 cells. In contrast, neither cell death nor any evidence of ICP0-induced toxicity was evident in both primary cultures of non-cycling cells. These observations suggest that ICP0 has gene therapy potential and would be the first member of a new family of cytostatic proteins that could be used to treat cancer [55].

A different approach used amplicons expressing siRNA in order to mediate post-transcriptional silencing of molecules involved in the pathogenesis of cancer or connected with the radiation resistance of tumour cells. Infected human glioblastoma cells with knockdown for the epidermal growth factor receptor (EGFR) expression displayed growth inhibition, both in culture and in athymic mice [56]. Besides, the combination of vector-mediated silencing of Rad51 expression (which is a key component of the homologous recombination repair of DNA double-strand breaks) and treatment with ionizing radiation, resulted in a pronounced reduction of human glioma cells survival in culture and in a significant decrease in tumour size in athymic mice [57].

Another tested strategy was to target tumour cells via transcriptional control of therapeutic genes. Ho and co-workers constructed a glioma-specific and cell cycle-regulated amplicon carrying the GFAP enhancer/promoter element, plus a cell cycle specific regulatory element from the cyclin A promoter [58]. Transgenic activity was mediated in a cell type-specific and cell cycle-dependent manner, both *in vitro* and *in vivo* in glioma-bearing animals [59]. Anti-tumour efficacy of this vector system was assessed using the pro-apoptotic proteins Fas ligand (FasL) and the Fas-associated death domain (FADD), inducing cell death in proliferating primary human glioma cells derived from patients, and resulting in prolonged survival of mice bearing orthotopic gliomas [60]. The authors pointed out that these vectors are stable, elicit minimal immune response and are not significantly hampered by chemotherapy or irradiation *in vivo* [58].

To achieve schwannomas regression without injury to associated neurons, it was generated an HSV-1 amplicon vector, in which the apoptosis-inducing enzyme caspase-1 (ICE), was placed under the Schwann cell-specific P0 promoter. Following direct intra-tumoral injection of the P0-ICE amplicon vector in an experimental xenograft mouse model (tumours were formed by subcutaneous injection of an immortalized human schwannoma cell line into one or both flanks of immunodeficient mice), there was a marked regression of schwannoma tumours. Injection of the same amplicon vector into the sciatic nerve produced no apparent injury to the associated dorsal root ganglia neurons or myelinated nerve fibers. Hence, the P0-ICE amplicon vector provides a potential means of 'knifeless resection' of schwannoma tumours by injection of the vector into the tumour, with low risk of damage to associated nerve fibers [61].

AMPLICON VECTORS AND VACCINES

In this section we present a brief summary about some applications of HSV-1 derived vectors as potential vaccines.

Wild-type HSV-1 is a potent immunogen that can elicit both host innate and adaptive immune responses [62], though is also able to evade host immunity due to immuno-modulatory gene products such as the ICP47 protein [63]. The biological characteristics of HSV-1 amplicons that make them an attractive candidate for vaccine delivery applications are: its safety profile, the lack of expression of viral immuno-evasive genes, large insert capacity and ability to infect a wide range of cells, including antigen-presenting cells. So far, immunization studies involving amplicons have been essentially directed against viral pathogens and neurological disease factors.

Virus-like particles (VLPs) are promising vaccine candidates, because they represent viral antigens in the authentic conformation of the virus particles and are, therefore, readily recognized by the immune system. As VLPs do not contain genetic material, they are safer than attenuated virus vaccines. In a first study, HSV-1 amplicon vectors were constructed to coexpress the rotavirus (RV) structural genes VP2, VP6, and VP7, and were used as platforms to launch the production of RV-like particles (RVLPs) in vector-infected mammalian cells. HSV-1 amplicon vectors launching the production of heterologous rotavirus-like particles were able to induce rotavirus-specific immune response in mice [25]. In a second study, amplicons expressing Foot-and-mouth disease (FMD) virus antigens were used to generate a genetic vaccine prototype, based in the *in situ* generation of FMD-VLPs [64].

Amplicons have been also used to express antigens and elicit immune responses in the context of veterinary diseases. In particular, specific serum antibody responses were detected in mice inoculated with amplicon vectors that expressed the glycoprotein D (gD) of bovine herpesvirus [24].

Most studies focused on immunization against HIV. Hocknell and colleagues showed that a single inoculation of 1×10^6 transducing units of amplicons expressing the HIV-1 envelope glycoprotein (gp120), was able to elicit strong, antigen-specific and long-lasting (≤ 5 months) cellular and humoral responses in mice [65]. Subsequent studies demonstrated that a combined heterologous prime-boost immunization approach using naked plasmid DNA prime and amplicon boost expressing the gp120 antigen could enhance by 15- to 20-fold the amplicon induced memory T-cell responses [66]. Gorantla and co-workers used non-obese diabetic/severe combined immunodeficient mice repopulated with human peripheral blood lymphocytes, as *in vivo* model for HIV immunization [67]. Injecting autologous dendritic cells transduced *ex vivo* with a gp120-expressing amplicon into these mice, resulted in primary HIV-1-specific humoral and cellular immune responses. The same authors demonstrated that there also was a partial protection against infectious HIV-1 challenge in the immunized mice [67]. Lastly, in an attempt to optimize amplicons for HIV vaccine delivery, Santos and collaborators showed that amplicons expressing the HIV-1 *gag* gene driven by two different HCMV hybrid promoters (HCMV/long-terminal repeat or HCMV/woodchuck post-regulatory element), elicited the strongest immune response in mice [68].

Other studies have explored the potential of amplicons in immunotherapy for prion disorders. Bowers and collaborators described the construction of amplicons expressing domains of PrP C fused to tetanus toxin Fragment C as adjuvant, as a base for prion disorders

immunotherapy [69]. Vaccination generated significant levels of prion protein (PrP)-specific antibodies in mice, but none of the constructions was able to alter disease progression.

Since amplicons can elicit strong antigen-specific immune responses to viral or mammalian proteins, they might be used in prophylactic vaccination against pathogens or neurodegenerative diseases. However, due to the high prevalence of HSV infection within the human population, one major concern about their use as vaccines is the possible impact of pre-existing antiviral immunity on vaccine efficiency. This question remains controversial. Some studies using replication-defective HSV-1 showed strong immune responses even in the presence of anti-HSV immunity [65, 70]. In contrast, another study with a replication-defective HSV-1, showed a substantial reduction in immune responses in animals previously vaccinated against HSV-1 [71].

AMPLICON VECTORS AND BEHAVIOUR

Amplicon vectors have been delivered into distinct brain regions to investigate complex aspects of the normal functioning of the central nervous system (CNS). Amplicon vectors designed to modify protein expression may carry sequences that allow overexpression or knockdown of an endogenous protein, or expression of an exogenous protein (e.g., dominant-negative mutants) relevant for CNS functions, like proteins directly involved in neurotransmission and in neuron signaling. A comprehensive review on the use of amplicons vectors to study behaviour can be found in Jerusalinsky and co-workers (2012) [20].

Different challenges to find causal relationships between neuronal molecular mechanisms and learning and memory processing, have been solved by the use of amplicon vectors. These vectors were used, for example, to investigate the involvement of NMDA glutamate receptor (NMDAR) in learning and memory. Amplicons carrying sequences in either sense or antisense orientations of the GluN1 subunit gene, in addition to EGFP as the reporter gene, were used to investigate the participation of hippocampal NMDAR by modifying the expression of that essential GluN1 subunit in the rat CNS. The ability to modify endogenous levels of GluN1 was first tested *in vitro* in primary cultures of neurons from rat embryo cerebral cortex [72, 73] and then assessed *in vivo*. Adult rats inoculated into the dorsal hippocampus with vectors expressing GluN1 antisense performed significantly worse than control rats in an inhibitory avoidance of a footshock task, and did not show habituation (decreased exploratory behaviour) by repeated exposure to an open field. Immunohistochemistry in serial brain slices from these animals, showed that the transduced cells represented approximately 6–7% of hippocampal pyramidal neurons in CA1 region and just about less than 1% of granule cells in the dentate gyrus, indicating that the knockdown of a single gene in a small number of those neurons significantly impaired memory [74].

Amplicon vectors expressing a constitutively active catalytic domain of the protein kinase C (PKC) β -II were used to transduce rat hippocampal dentate granule neurons. Activation of PKC pathways in a small percentage of these neurons was sufficient to enhance rat auditory discrimination reversal learning, suggesting an hippocampal auditory mediated learning in the rat [75].

Amplicon vectors have been used to elucidate the role of the alpha-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid receptor/channel (AMPA) in learning and memory

processes. Most endogenous AMPARs contain the GluR2 subunit and both inward and outward currents can pass through equally well. In contrast, AMPARs lacking GluR2 exhibit a profound inward rectification, what means that minimal outward current could pass through these channels when the cell depolarizes. Thus, incorporation of recombinant AMPARs into synapses can be monitored functionally [76]. To study the AMPARs trafficking in associative fear conditioning learning, Rumpel and co-workers injected amplicon vectors expressing recombinant AMPARs subunits into the rat basolateral amygdala [77]. An amplicon vector encoding GluR1 subunit fused with GFP was used to express homomeric AMPARs, which display greater inward rectification than endogenous AMPARs, allowing electrophysiological detection of synapses undergoing plasticity by incorporation of recombinant GluR1-AMPA. Another amplicon vector encoded the carboxyl cytoplasmic tail of GluR1 subunit fused with GFP, expressing a protein that acts as a dominant-negative construct to prevent synaptic incorporation of endogenous GluR1-receptors, and thereby blocks several forms of synaptic plasticity *in vitro* and *in vivo*. A third vector driving expression of GFP only, was used as control of infection. Using these vectors, they showed that fear conditioning drives AMPARs into the synapse of a large fraction of post-synaptic neurons in the basolateral amygdala, and that blocking GluR1-receptor trafficking in a few (~10 to 20%) neurons undergoing plasticity, was sufficient to impair memories depending on this structure [77].

The cyclic adenosine monophosphate (cAMP) response element-binding protein (CREB) plays an important role in learning and memory processes [78]. It was shown that changes in CREB function could influence the probability of individual lateral amygdala neurons to be recruited into a fear memory trace, suggesting a competitive model underlying memory formation. In such a model, eligible neurons are selected to participate in a memory trace as a function of their relative CREB activity in learning [79]. In this regard, several investigators have manipulated the function of CREB using amplicons vectors. An amplicon encoding wt-CREB was used to show that increasing CREB in the auditory thalamus enhanced memory and generalization of auditory conditioned fear, indicating that CREB-mediated plasticity in the thalamus plays a role in this cognitive process [80]. Using an amplicon vector encoding a dominant-negative mutant form of CREB (mCREB), Brightwell and collaborators demonstrated that hippocampal overexpression of mCREB can block long-term – though not short-term – memory for a socially transmitted food preference, therefore involving hippocampal CREB function in this type of memory [81]. They later showed that rats trained to make a consistent turning response in a water version of the plus maze, required CREB function in the dorsolateral striatum to form a long-term memory of the response strategy, and showed that it is independent on CREB function in the dorsal hippocampus [82]. Using a model of protracted social isolation in adult rats, Barrot et al. observed an increase in anxiety-like behaviour and in both the latency of the onset of sexual behaviour and the latency to ejaculate [83]. Then, in transgenic cAMP response element (CRE)-LacZ reporter mice, which express β -gal under control of CREs, they showed that protracted social isolation also reduced CRE-dependent transcription within the nucleus accumbens. This decrease in CRE-dependent transcription was mimicked in non-isolated animals by amplicon-based gene transfer of a dominant-negative mutant of CREB into the nucleus accumbens. In these animals, the local inhibition of CREB activity increased anxiety-like behaviour and delayed initiation of sexual behaviour, with no effect observed on the ejaculation parameters. In isolated animals, restoring CREB activity in the nucleus accumbens using amplicon vectors to overexpress wt-CREB, rescued the anxiety phenotype as well as the deficit in the latency to initiate sexual behaviour.

This study suggests a role for the nucleus accumbens in anxiety responses and in specific aspects of sexual behaviour, and provides novel insights into the molecular mechanisms by which social interactions affect brain plasticity and behaviour [83].

Interestingly, Liu and co-workers recently reported that an amplicon expressing siRNA for the γ -Aminobutyric acid A (GABA-A) receptor $\alpha 2$ subunit, infused into the central nucleus of the amygdala of alcohol-preferring rats, (*i*) caused profound and selective reduction of binge drinking associated with inhibition of $\alpha 2$ subunit expression, (*ii*) decreased GABA-A receptor density and (*iii*) inhibited Toll-like receptor 4 (TLR4) expression [84]. Furthermore, infusion of an amplicon expressing TLR4 siRNA into the central amygdala also inhibited binge drinking, but did not cause such changes when infused into the ventral pallidum. On the other hand, binge drinking was effectively inhibited by an amplicon expressing GABA-A receptor $\alpha 1$ subunit siRNA, infused into the ventral pallidum, showing that TLR4 contributes to binge drinking downstream to $\alpha 2$ subunit in the central amygdala, but not in the ventral pallidum, underscoring the relevance of TLR4 in specific neuroanatomical sites. Those data indicate that GABA-A $\alpha 2$ -regulated TLR4 expression in the central amygdala contributes to binge drinking and may be a key for early neuroadaptation in excessive drinking [84].

AMPLICON VECTORS AND NEURODEGENERATIVE DISEASES

Ataxias

Ataxias are a group of specific degenerative diseases of the nervous system characterized by the loss of movement coordination. Hereditary ataxias could be recessive or dominant. Nowadays, no treatment can effectively stop progression of ataxias.

The most prevalent form of hereditary ataxia is the Frederich's ataxia (FA) [85], where neurological symptoms result from neurodegeneration in the dorsal root ganglia (DRG), with loss of large sensory neurons and posterior columns, followed by degeneration in the spinocerebellar and corticospinal tracts of the spinal cord. This disease is caused by a mutation in the first intron of the frataxin gene (*frda wt*) which causes a large GAA repeat expansions (*frda mut*) and, in consequence, leads to a decrease in the level of the mitochondrial protein, frataxin.

Lim and collaborators generated a conditional frataxin transgenic mouse with the *frda wt* gene floxed (*loxP-frda*); then, they injected an amplicon vector carrying the CRE recombinase transgene into the brainstem of this transgenic *loxP-frda* mouse [86]. CRE expression causes the homologous recombination of loxP sites and the loss of *frda*, leading to a decrease in frataxin expression. These mice developed behavioral deficits after 4 weeks, resembling FA. In an attempt to generate a treatment for FA, the authors injected a second amplicon vector, bearing the cDNA of *frda wt*. These mice exhibit behavioral recovery as early as 4 weeks after the second vector injection [86].

Taking advantage of the large capacity of amplicon vectors, Gomez-Sebastian and collaborators used amplicons to deliver a 135-kb insert containing the entire *frda wt* human genomic locus, including long upstream and downstream regulatory sequences (~80-kb), to fibroblasts extracted from FA patients (which expressed low levels of frataxin) [87]. Synthesis of frataxin in these *frda wt*-transduced FA-deficient cells was confirmed by

immunofluorescence [87]. The fibroblasts of FA patients have been shown to exhibit biochemical deficits, including increased sensitivity to oxidative stress. Functional complementation studies demonstrated restoration of the wild type cellular phenotype in the *frda* wt-transduced cells, in response to H₂O₂ treatment (a classical stressor) [87].

To investigate the persistence of the transgene expression, the same group injected into the adult mouse cerebellum an iBAC-HSV-1-based vector, carrying the 135-kb *frda* wt genomic DNA locus [88]. As reporter, the authors constructed another vector, but with the *E. coli lacZ* gene inserted at the ATG start codon (iBAC-*frda-lacZ*). Direct intracranial injection of this vector into the adult mouse cerebellum resulted in a large number of cells expressing *lacZ*; this expression was driven by the *frda* wt locus and persisted for at least 75 days. In contrast, synthesis of GFP expressed from the same vector, but driven by the HSV-1 IE4/5 promoter, was strong but transient. This study demonstrated for the first time, a sustained transgene expression *in vivo*, by amplicon delivery of a very long genomic DNA locus. All together these results suggest the potential of the HSV-1 derived-*FRDA* vectors for gene therapy of FA.

Ataxia-telangiectasia is an autosomal recessive neurodegenerative disorder due to mutations in the A-T gene (*AT*). This gene is, in the AT wt form, a kinase responsible for recognizing and correcting errors in current DNA duplication before cell division. Several mutations led to an AT-mutated: (ATM) protein with different degrees of activity, generating a pleiotropic phenotype characterized by cerebellar degeneration, immunodeficiency, cancer predisposition, increased radiation sensitivity and premature aging, according to the residual kinase activity of the expressed ATM protein [89]. As the *AT* cDNA is too large (~9-kb) for most of the currently used vectors, it was difficult to rescue the phenotype of cells expressing ATM. Therefore, Cortes and co-workers used an amplicon vector codifying the *AT* cDNA, to express a non-mutated form of AT in human fibroblasts which express ATM [90]. The AT wt protein expression was confirmed by western blot and immunofluorescence. AT kinase function was tested by *in vitro* phosphorylation of p53; the *in vivo* functionality of AT was assessed by counting the accumulation of G2/M cells after ionizing radiation [90].

In a further study, the same group constructed an amplicon encoding both the EGFP and a human FLAG-tagged-AT protein; this vector was inoculated in the cerebellum of AT^{-/-} mice. The number and phenotype of infected cells were assessed by EGFP fluorescence and infection of thousands of cells at the inoculated cerebellum, including Purkinje cells, was confirmed. FLAG-tagged-AT expression was demonstrated at transcriptional (qRT-PCR, *in situ* hybridization) as well as at translational (immunoprecipitation of the full-length human protein) levels, 3 days post-inoculation [91].

In an attempt to achieve stable gene replacement, the same group generated an HSV/adeno-associated virus (AAV)-hybrid amplicon, carrying the expression cassette for the AT and EGFP cDNAs, flanked by AAV inverted terminal repeats (ITRs). In the presence of the AAV Rep proteins (proteins codified by AAV genome, required for AAV chromosome integration), this hybrid vector mediated a site-specific integration of the transgenic sequences into the AAV1 site of chromosome 19. To test functional activity of this AT vector, Cortes *et al.* exposed AT infected cells to ionizing radiation; then, AT activity was assessed by specific immunofluorescence using antibodies against the phosphorylated form of AT (pAT, activated form). An increase in pAT was observed only in AT-AAV/HSV infected cells and not in cells infected with a control vector [92]. These results showed that this AT HSV/AAV hybrid amplicon was able to integrate into the AAVS1 site and to achieve functional expression of human AT cDNA *in vivo*, in a mouse model of ATM.

Alzheimer Disease

One of the most studied neurodegenerative diseases is Alzheimer's disease (AD). In this pathology, the peptide known as amyloid beta ($A\beta$) acts as a neurotoxin that produces neurodegeneration. More precisely, a recently enunciated hypothesis states that soluble oligomers of $A\beta$ peptide (named ADDLs: $A\beta$ -derived diffusible ligands) bind to neurons, mainly at the post-synaptic side, and that this binding would be responsible for triggering toxic effects that ultimately lead to neuronal death [93, 94].

$A\beta$ peptide is generated by degradation of the Amyloid Precursor Protein (APP). Under physiological conditions, APP is first cleaved by α -secretase and subsequently cleaved by γ -secretase, resulting in a non-amyloidogenic soluble peptide. However, under certain abnormal conditions or by blocking the normal degradation pathway, APP is cleaved by the β -secretase BACE-1 (instead of α -secretase) and then by the γ -secretase, generating amyloidogenic peptides 1-40 and 1-42, (of 40 and 42 amino acids respectively, being $A\beta$ 1-42 more amyloidogenic than $A\beta$ 1-40) [95]. $A\beta$ initially aggregates in soluble oligomers of 2–14 monomers (ADDLs), which can bind to the post-synaptic densities; then, as the concentration rises up, they further aggregate into fibrils in the extracellular space and then form the typical amyloid plaques [94, 96-100].

Two studies have described the use of amplicons for " $A\beta$ vaccination" in mice as a possible therapeutic strategy for AD, aimed at preventing $A\beta$ fibrillogenesis and/or to enhance removal of parenchymal amyloid deposits. In the first study, transgenic Tg2576 mice, which overexpress APP with the Swedish mutation that results in enhanced generation and extracellular deposition of the $A\beta$ 1–42 peptide, were injected with amplicons expressing either $A\beta$ 1-42 (HSVA β) or $A\beta$ 1-42 fused to the molecular adjuvant tetanus toxin Fragment C (HSVA β /TtxFC). Peripheral administration of both "vaccines" augmented humoral responses to $A\beta$ and reduced CNS $A\beta$ deposition in this model of AD. However, HSVA β vaccination was found to be toxic, since it induced expression of pro-inflammatory transcripts within the mouse hippocampus [101].

Another amplicon vector -HSV(IE) $A\beta$ (CMV)IL-4-, was constructed to co-delivered $A\beta$ 1-42 and interleukin 4 (IL-4), a cytokine that promotes the generation of Th2 like T-cell responses. Triple transgenic AD (3XTg-AD) mice, which progressively develop both amyloid and neurofibrillary tangle pathology, were vaccinated with that vector or with a set of control amplicon vectors (one encoding $A\beta$ 1–42 but not IL-4, and one "empty" vector without $A\beta$ 1–42 or IL-4 transgenes). Prevention of AD-related amyloid and tau pathology progression were significantly more important in HSV(IE) $A\beta$ (CMV)IL-4 treated mice than in control groups. Furthermore, the expression of Th2-related $A\beta$ -specific antibodies appeared to improve learning and memory in the Barnes Maze spatial memory paradigm [102]. Therefore, these results underlined the potential of amplicons for $A\beta$ immune-therapy of AD [103].

Neurodegenerative pathologies as AD or Parkinson's disease (PD), as well as some forms of depression, have been associated to dysfunction of receptor-neurotransmitter systems. L-glutamate is the major excitatory neurotransmitter in the CNS. Therefore, glutamate receptors represent an attractive molecular target in the treatment of neurodegenerative diseases and also in epilepsy, schizophrenia and ischemia.

There is recent evidence showing that the transmembrane protein APP appears capable of interacting with NMDAR [104, 105]. These ionotropic receptors are tetramers made of two GluN1 subunits and different GluN2 (A-D), and/or GluN3 (A-B) subunits, with GluN1 being

essential for receptor assembly [106-108]. Nowadays, association of NMDAR with several neuropathologies has been continuously growing up. Thus, the generation of novel tools that modify expression and composition of NMDARs should help to understand both the normal functioning (as reported above in “*Amplicon vectors and behaviour*” section) and the physiopathology of these receptors. It was proposed that ADDLs binds to NMDAR or to post-synaptic complexes containing it, acting as gain of function ligands [93, 94, 109]. By targeting such post-synaptic complexes, ADDLs activate a cascade of signals that lead to an increase in intracellular reactive oxygen species (ROS) [93]. Decker and colleagues have demonstrated that blockade of GluN1 expression through the infection of primary cultured neurons with amplicon vectors encoding an anti-GluN1 antisense RNA, inhibited ADDLs binding to synapses [109]. In the same study, they showed that there was a great reduction in ADDL-instigated ROS formation in GluN1 knockdown neurons [109]. In addition, it has recently been reported that different regulatory GluN2 subunits would also be involved in the binding of ADDLs to synaptic sites [110, 111]. Liu and colleagues have suggested that increasing the activity of GluN2A and/or reducing that of GluN2B, may alter or reduce the expression of cytotoxic effects mediated by ADDLs in neuronal cultures [110]. On the other hand, Balducci and colleagues showed that there was an alteration in the trafficking of GluN2A and GluN2B subunits in mutant mice expressing an amyloidogenic human form of APP [111]. However, more precise studies on the possible specific interaction between different subunits of the NMDAR and the A β peptide, both in normal and pathological conditions, is necessary to further clarify the specific site for ADDLs binding. It should be taken into account that the decrease in GluN1, which is essential for assembly and for the membrane allocation of the receptor, would lead to a decrease of all the NMDAR subunits at the synaptic surface [112].

The genes for microtubule-associated protein tau (*MAPT*) and α -synuclein (*SNCA*) play central roles in neurodegenerative disorders. Peruzzi and colleagues have recently generated amplicon-based iBAC-vectors carrying either the 143-kb *MAPT* or the 135-kb *SNCA* loci [113]. They have used these vectors to study regulation of gene expression of both *MAPT* and *SNCA*, showing functional complementation between them in cultured neurons and in organotypic brain slices. Infected neurons were able to express functional genes under physiological regulation, including the generation of multiple splice variants. In particular, multiple *MAPT* transcripts were expressed under strict developmental and cell type-specific control. Primary cultures from *Mapt*($-/-$) embryos had been shown to be resistant to A β peptide-induced toxicity, suggesting that the tau protein might be mediating the neurotoxicity of A β . To test the functionality of the *MAPT* transgene, the authors examined whether the responsiveness to A β peptide could be restored in the *Mapt*($-/-$) neurons and in organotypic brain slices. In both preparations from *Mapt*($-/-$) mice infected with the vector bearing the *MAPT* transgene, the tau protein was expressed as detected by ELISA and immunocytochemistry, and the sensitivity of *Mapt*($-/-$) neurons to A β peptide was restored [113]. As stated by the authors, the faithful retention of gene expression and phenotypic complementation by this system provides a novel and powerful approach to analyze neurological disease genes.

Parkinson Disease

Parkinson's disease (PD) is the second most common neurodegenerative disorder. A typical feature of this disease is the progressive loss of dopaminergic neurons in the substantia nigra

and a decrease in the level of dopaminergic inputs to the striatum [114]. PD is clinically characterized by akinesia or bradykinesia, rigidity and tremor that are directly related to dopaminergic striatal loss [115]. Several studies have used amplicons in experimental settings of PD. During and co-workers were the first to report the use of amplicons to deliver human tyrosine hydroxylase (TH) into the partially denervated striatum of 6-hydrodopamine-lesioned rats, used as a model of PD [116]. Efficient behavioral and biochemical recovery has persisted for one year after gene transfer.

In an attempt to improve that vector, Sun and collaborators developed another vector able to co-express two enzymes involved in the synthesis of L-DOPA: TH and the aromatic amino acid decarboxylase (AADC), under a modified neurofilament gene promoter that supports long-term expression in forebrain neurons [117]. This improved vector was injected in the right striatum of adult rats where PD-like symptoms had been previously induced by injection of 6-OHDA in the substantia nigra. Histologic analyses demonstrated neuronal-specific coexpression of TH and AADC from 4 days to 7 months after gene transfer. In these rats, vector injection was able to correct in about 80% the apomorphine-induced rotational behaviour present in this 6-OHDA rat model of PD [117]. Later on, in a series of elegant studies, Sun and co-workers further compared the activities of tissue-specific promoters to drive gene expression, particularly the promoters of TH, the neurofilament and the vesicular glutamate transport 1 (VGLUT1) [22, 118-122]. Taking advantage of the large transgene capacity of HSV derived vectors, they developed two vectors: one that co-express the three dopamine biosynthetic enzymes (TH, GTP CH I, and AADC, a 3-genes-vector) and another carrying all the three dopamine biosynthetic enzymes and the vesicular monoamine transporter (TH, GTP CH I, AADC, and VMAT-2, a 4-genes-vector). The authors compared the effects of both vectors. The 4-genes-vector supported higher levels of correction of apomorphine-induced rotational behaviour than did the 3-genes-vector, and this correction was maintained for 6 months. Proximal to the injection sites, the 4-genes-vector, but not the 3-genes-vector, supported extracellular levels of dopamine and dihydroxyphenylacetic acid (DOPAC) similar to those observed in normal rats, and only the 4-genes-vector supported significant K⁺-dependent release of dopamine [118].

The effect of amplicon-mediated transduction of the dominant-negative fibroblast growth factor (FGF) receptor-1 mutant protein (FGFR1(TK-)) into the rat substantia nigra, was evaluated *in vivo* as a possible strategy to mimic the reduced FGF signaling already documented to occur in PD. Following intra-nigral delivery of the FGFR1(TK-) amplicon, the number of substantia nigra neurons expressing TH was significantly reduced, leading to the conclusion that reduced FGF signaling in the substantia nigra of Parkinsonian patients could play a role in the impaired dopaminergic transmission in PD [123]. In a further study, the same group analyzed the effect of *ex vivo* transduction of mesencephalic reagggregates with the anti-apoptotic protein bcl-2, on grafted dopamine neuron survival. Using an amplicon expressing bcl-2 under the control of the TH promoter (HSV-TH9bcl-2) to transduce mesencephalic reagggregates, it was shown that, in spite of the high efficiency of the infection (since many cells were effectively transduced), amplicon-mediated overexpression of bcl-2 did not lead to an increase in grafted TH-immune-reactive neuron number [124].

Mitochondrial alterations are detected in most neurodegenerative disorders and may contribute to the dysfunction and demise of neurons. Rotenone or 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridina (MPTP) inhibit the mitochondrial complex I, causing death of dopaminergic neurons in the substantia nigra, thus providing an acute model of PD. It has been recently

demonstrated that mitochondrial hexokinase II promotes neuronal survival in rotenone treated cells, and that this enzyme acts downstream of glycogen synthase kinase-3 (GSK-3), which is considered to be a critical factor in regulating neuronal cell survival and death [125]. More recently, the same group generated amplicons expressing hexokinase II; overexpression of this protein in the substantia nigra of mice subsequently administered with rotenone or MPTP, prevented neuronal cell death induced by both drugs and reduced the associated motor deficits. These results provide the first proof that hexokinase II could protect against dopaminergic neurodegeneration *in vivo*, and suggest that increase of hexokinase II expression could represent a promising approach to treat PD [126].

Narcolepsy

Narcolepsy is a neurodegenerative sleep disorder that is linked to the loss of neurons containing the neuropeptide orexin (also known as hypocretin). Liu and collaborators inoculated an amplicon vector expressing pre-pro-orexin into the lateral hypothalamus of orexin knockout mice and showed that exogenous expression of orexin significantly improved sleeping in these animals [127].

AMPLICON VECTORS AND NERVOUS SYSTEM DAMAGE

Ischemia

Apoptosis plays a critical role in many neurological diseases, including stroke. To study the protective role of the antiapoptotic factor *bcl-2* in ischemia, an amplicon vector encoding *bcl-2* (HSV**bcl-2**) was infused in rat cerebral cortex 24 hours prior to ischemia induction. Expression of *bcl-2* was confirmed by immunohistochemistry in animals injected with the HSV**bcl2** expression vector. Tissue viability significantly increased at the injection site in HSV**bcl2**, but not in animals injected with a similar vector expressing *E. coli* LacZ (HSV**LacZ**) [128]. Later, HSV**bcl-2** was used to inject gerbils unilaterally into the CA1 region of the hippocampus, 24 hours prior to induce transient global ischemia [129]. Results showed that the local increase in *bcl-2* expression using the HSV**bcl-2** vector, may protect CA1 pyramidal cells from the delayed neuronal death caused by transient global ischemia, and that this happened only in the HSV**bcl-2** injected hemisphere. In the same line, other group generated another *bcl-2* expressing amplicon that was used to infect hippocampal cell cultures. *Bcl-2* expressing vectors enhanced neuron survival after exposure to adriamycin, glutamate and hypoglycemia. Furthermore, dichlorofluorescein measurements indicated that there was a significant reduction in the accumulation of oxygen radicals associated with these insults [130]. Improved neuron survival could be attributed to the fact that the *bcl-2* blocks nuclear Apoptosis-inducing factor (AIF) translocation [131]. In an experimental therapeutic approach, Lawrence and collaborators injected rats with this *Bcl-2* expressing vector after ischemia induction, then leading to a reduction in neuronal loss [132]. Furthermore, they showed that there is a time window (30 minutes to 4 hours after reperfusion) where the injection was effective [132]. In accordance with these results, amplicon vectors expressing the inducible heat shock protein (hsp) 72 can also attenuate cerebral ischemic injury when introduced into the rat striatum, even during post-

ischemia [133]. Furthermore, amplicons expressing hsp72 also protected neurons of CA1 hippocampal region from ischemia, and this protection would be mediated, at least in part, by increased expression of bcl-2 [134].

Neurotoxicity

Increases in cytoplasmic Ca^{2+} concentration can lead to neurotoxicity and neuronal death. The increase of Ca^{2+} could be induced by neurological trauma associated with aging and some neurological diseases. To prevent neurotoxic effects of cytoplasmic Ca^{2+} increases, an amplicon vector that expresses the calcium-binding protein calbindin D28K (calbindin D28KHSV) was used to infect neurons, both *in vitro* and *in vivo* [135, 136]. Cultured neurons infected with this vector responded to hypoglycemia and glutamatergic insults with decreased cytoplasmic $[\text{Ca}^{2+}]$ measured by microfluorometry and increased neuron survival relative to controls [135]. Furthermore, *in vivo* injection of calbindin D28KHSV vector in the hippocampal dentate gyrus increases neuronal survival after application of the antimetabolite 3-acetylpyridine, and increases transynaptic neuronal survival in area CA3 following kainic acid neurotoxicity [136].

Reactive oxygen species (ROS) and oxidative stress damage plays an important role in neuronal death. Amplicon vectors expressing different antioxidant enzymes were used to counteract oxidative damages. The cDNA of catalase and glutathione peroxidase, two enzymes involved in hydrogen peroxide degradation, were subcloned into amplicon vectors. These vectors were shown to decrease neurotoxicity induced by different agents in primary cultures of hippocampus or cerebral cortex cells [137]. A further study using amplicons to express the antioxidant enzyme Cu–Zn–SOD, showed that these vectors were able to protect hippocampal neurons through the induction of glutathione peroxidase expression, though only in the case of neurons treated with sodium cyanide. The authors pointed out that the effect of the amplicons actually worsens the toxic effects of kainic acid, another classical ROS inducer, raising a cautionary note concerning gene therapy against oxidative damage [138]. Amplicons expressing glutamic acid decarboxylase (GAD67) were shown to protect non-differentiated cortical neurons from glutamate toxicity mediated by oxidative stress [139].

It was reported that the HIV glycoprotein of 120kDa (HIV-gp120) could be neurotoxic at certain doses and that the hsp70, hsp25 or hsp90 overexpression would protect neurons from HIV-gp120 effect. Therefore, Lim and collaborators overexpressed hsp70 with a HSV-amplicon vector in cultured hippocampal neurons; in this way, they demonstrated that hsp70 overexpression protected cultured hippocampal neurons from HIV-gp120 neurotoxicity [140].

Hypoglycemia could result in an insult for neurons. With amplicons expressing the rat brain glucose transporter (GT), it was shown that these vectors: (i) can maintain neuronal metabolism and reduce the extent of neurons loss in cultures, after a period of hypoglycemia [141]; (ii) protected cultured hippocampal, spinal cord and septal neurons against various necrotic insults, including hypoglycemia, glutamate and 3-nitropropionic acid [142]; and (iii) can enhance glucose uptake in adult rat hippocampus and in hippocampal cultures [143].

Neurotrophins

Neurotrophins are a family of growth factors that play important roles in the development and maintenance of the nervous system. The human brain-derived neurotrophic factor (BDNF) is one of the most important neurotrophins. The knowledge about the complex function of BDNF in mammalian nervous system is continuously expanding; it plays a key role as mediator of activity-induced long term potentiation (LTP) in the hippocampus, as well as in behaviour and memory [144]; BDNF has been implicated in neurodegenerative diseases [145], motor diseases [146] and fragile X syndrome [147]. This neurotrophin participates in maturation and function of mammalian auditory neurons. For this reason, amplicon vectors expressing BDNF were used to evaluate the feasibility of gene therapy of deafness. First, Geschwind and collaborators used an amplicon vector bearing a BDNF cDNA and *E. coli* β -galactosidase (HSVbdnflac), to evaluate the expression and biological activity in established cell lines and explant cultures, prepared from spiral ganglia of the murine ear [148]. Using two BDNF-responsive cell lines, PC12trkB and MG87trkB, they demonstrated efficient secretion of biologically active BDNF [148]. Also, the transduction of explanted spiral ganglia with HSVbdnflac, elicited a robust neuritic process outgrowth, that is comparable to the effect of exogenously added BDNF [148]. Later on, the amplicon vector expressing BDNF was used in mice to infect damaged spiral ganglion. Four weeks post-infection, stable production of BDNF was observed; and it supported the survival of auditory neurons by preventing their loss due to trophic factor deprivation-induced apoptosis [149]. In addition, the use of amplicons expressing BDNF promoted neuronal survival up to the same maximal level seen by adding exogenous BDNF, in a model of avian cochlear neuron cultures [150]. Other neurotrophins were implicated in the proper function of the auditory system. Amplicons expressing neurotrophin-3 (NT-3) were also used in murine cochlear explants model. After infection, the cochlear explants were exposed to cisplatin to induce destruction of hair cells and neurons in the auditory system. This toxicity, defined as ototoxicity, is a major dose-limiting side effect of cisplatin chemotherapy for cancer patients. Amplicon-mediated NT-3 transduction was shown to attenuate the ototoxic action of cisplatin, demonstrating the potency of NT-3 in protecting spiral ganglion neurons from degeneration [151]. Moreover, aged mouse injected in the peripheral auditory system with amplicon vectors expressing NT-3, showed significantly more spiral ganglion surviving neurons (SGNs) and lower incidence of cisplatin-induced apoptosis or necrosis, than those injected with a control vector [152]. Therefore, this approach seemed to be a promising treatment for prevention of chemical-induced hearing disorders and potentially for hearing degeneration due to normal aging.

Amplicon vectors were used to compare BDNF ability with that of the glial-derived neurotrophic factor (GDNF) to protect nigrostriatal neurons in a rat model of PD. According to this study, GDNF was significantly more effective than BDNF for both correcting behavioral deficits and protecting nigrostriatal dopaminergic neurons. The expression of both neurotrophic factors from the same vector was not more effective than expressing GDNF only [153]. In a further study addressing the effect of this trophic factor, it was shown that intracerebral administration of amplicon vectors expressing GDNF, following prior occlusion of the middle cerebral artery, displayed neuroprotection in ischemic injury. Treated animals showed reduced motor deficits and, after 1 month, there was a reduction in tissue loss, in glial fibrillary acidic protein (GFAP) and in caspase-3 immunostaining [154].

In neonatal rats, the combined delivery of NT-3 and the GluN2D subunit of the NMDA receptor, that was possible thanks to the large capacity of amplicon vectors, was used to strengthen monosynaptic connections in contused cords and to induce the appearance of weak but functional multi-synaptic connections, in double hemi-sected cords. On the other hand, the expression of either NT-3 or GluN2D alone failed to induce appearance of synaptic responses through the hemi-sected region of newborn rats [155]. More recently, the same group has treated adult rats with the following agents: (i) anti-Nogo-A antibodies to neutralize the growth-inhibitor Nogo-A; (ii) NT-3 via engineered fibroblasts, to promote neuron survival and plasticity; and (iii) the GluN2D subunit via an HSV-1 amplicon vector, to elevate NMDA receptor function by reversing its Mg^{2+} blockade, thereby enhancing synaptic plasticity and promoting the effects of NT-3 [156]. The combined treatment resulted in slightly better motor function in the absence of adverse effects (i.e., pain), suggesting that this novel combined treatment may help to improve function of the damaged spinal cord [156].

Neuropathic Pain

Neuropathic pain is a chronic form of pain that results from an injury to the nervous system. It could be due to multiple causes, like alcoholism, chemotherapy, diabetes, facial nerve problems among others. Amplicon vectors expressing proenkephalin (pHSV-hPPE-lacZ, SHPZ), were used to investigate the antinociceptive effect of leu-enkephalin (a product of proenkephalin processing). The amplicons were injected into the ventral periaqueductal grey [157] or into the cortex of rats [21]. Both studies showed that the injection of SHPZ, but not of a control vector only expressing the reporter gene lacZ, attenuated neuropathic pain and reduced induced hypersensitivity in rats [21, 157].

ACKNOWLEDGMENTS

ALE and DAJ would like to thank the French *CNRS* and the Argentinean *CONICET* institutions for supporting the International Associated Laboratory (LIA) DEVENIR. Part of this work was supported by *Association Française contre les Myopathies* (AFM). MEM PhD studies were supported by AFM. CAB participation in this work was supported by the French Embassy in Argentina with a “*Bernardo Houssay*” postdoctoral position.

ABSTRACT

Papillomaviruses (PVs) infect the epithelium of amniotes, where they can cause tumours or persist asymptotically. PVs are classified in the *Papillomaviridae* family, that contains 29 genera of PVs isolated from humans (120 types), non-human mammals, birds and reptiles (69 types). PVs have circular double-stranded DNA genomes approximately 8 kb in size and typically contain eight genes. Studies aiming the identification of PVs genomes use techniques such as PCR with consensus primers, rolling circle amplification and metagenomic methods. Advances in papillomaviral genome research have allowed the knowledge of PVs diversity and evolution of the poorly known PVs genera types, revealing that there is still a limited understanding of PVs diversity. Particularly, recent studies in Bovine Papillomavirus (BPV) have shown the identification of novel BPV types and several putative new virus types in cattle. This chapter will show new contributions in PVs genome studies.

Keywords: Papillomavirus, molecular techniques, viral metagenomics

INTRODUCTION

Papillomavirus (PVs) is a group of viruses that induce warts (or papillomas) in a variety of animals. The PVs are widespread in nature and have been recognized primarily in higher vertebrates. Viruses have been characterized from humans, cattle, rabbits, horses, dogs, sheep, elk, deer, nonhuman primates, the harvest mouse, and the multimammate mouse (*Mastomys natalensis*) [1]. Some PVs also have malignant potential for animals and people. A

number of Human Papillomaviruses (HPVs) have been implicated as the etiologic agents for cervical cancer and other epithelial tumors.

PVs are small, nonenveloped, icosahedral DNA viruses that replicate in the nucleus of squamous epithelial cells. The virions consist of a single molecule of double-stranded circular DNA about 8,000 bp in size, contained within a spherical capsid coat, composed of 72 capsomers. The genome of the PVs can be divided, in general, into three major regions: early, late, and a long control region (LCR or noncoding region [NCR])[2]. The late region of the viral genome is expressed only in differentiated layers of warts and other productive lesions, while the early region express both in warts and transformed cells [2,3]. The products of the early region encode viral regulatory proteins, including those viral proteins that are necessary for initiating viral DNA replication and transformation of the host cell [4]. The late region of PVs genomes lies downstream of the early region and encodes L1 and L2 ORFs for translation of a major (L1) and a minor (L2) capsid protein. The LCR region has no protein-coding function, but bears the origin of replication as well as multiple transcription factor binding sites that are important in regulation of RNA polymerase II-initiated transcription from viral early as well as late promoters [5].

PVs have often been classified primarily accordingly to the host species they infect and the sites or diseases with which they are associated. DNA sequencing of many PVs genomes has led their phylogenetic organization, according to the comparative homology of the L1 ORF [6]. The L1 gene is useful for classification and construction of phylogenetic trees, as it is reasonably well conserved and can be aligned for all known PVs [7].

These similarities are consistent with the conclusion that PVs have accompanied their host species during evolution and have evolved with them [8]. Although all PVs share similar genetic organization, the L1 DNA sequence identity is just above 40% between the most divergent genomes. PVs were designated as a distinct family, *Papillomaviridae*, in the 7th Report of the ICTV [9]. De Villiers et al. [6] described the topology of phylogenetic trees based on the nucleotide sequence comparisons and biologically distinguishing features (host species, target tissues, pathogenicity, and genome organization) that determine the classification of PVs on the level of genera.

A nomenclature of these genera based on the Greek alphabet was introduced and has rapidly become accepted and widely used by the ICTV and community of PVs researchers.

Sixteen groups of PVs or individual PVs fulfilled the criterion of genera, and the Greek alphabet from the letters alpha to pi was employed to create their nomenclature. The last official classification of PVs genera ended with the genus Pi-PVs. The description of 13 new PVs genera however, exhausts the Greek alphabet. In order to create a system that continues with the Greek alphabet, it was proposed the use of the Greek alphabet a second time, employing the prefix “dyo”, (i.e., Greek “a second time”) [7].

Within a given genus, the L1 DNA of all members shares more than 60% identity. A viral type with a species has 71 to 89% identity with other types within the species. Within a type can exist subtypes, which share 90 to 98% identity, and variants, which have more than 98% identity [7].

Viruses can be identified by a wide range of techniques. Traditional methods include electron microscopy, cell culture, inoculation studies and serology [10].

Whereas many of the viruses known today were first identified by these techniques, the methods have limitations. For these viruses, the molecular-based techniques provide sensitive and rapid means of virus detection and identification [11].

One such approach uses sequence information from known types to identify related but undiscovered types through cross-hybridization. Another advance has involved PCR amplification of the viral genome. Such PCR-based methods comprise conventional PCR, degenerate PCR, sequence-independent PCR, and rolling circle amplification (RCA). Technological advances have also resulted in the development of metagenomics, the culture-independent study of the collective set of microbial populations in a sample by analyzing the sample's nucleotide sequence content [10].

In the next sections, it will be presented the main strategies for the identification of new types and variants of PVs and a particular broach about the recent advances in the Bovine Papillomavirus (BPV) research.

STRATEGIES USED TO IDENTIFY PAPILLOMAVIRUS GENOMES

Since PVs life cycle requires keratinocyte differentiation, there are no conventional cell lines that allow the growth these viruses [12]. Moreover, PVs could not be transmitted to laboratory animals [13]. Hence, molecular methods have been widely used to discover and characterize the genome of new PVs as well as for diagnostics of PVs that are clinically relevant [14–37].

Among these, molecular methods such as polymerase chain reaction (PCR), hybridization, and metagenomic methodologies have been frequently used in order to detect human [14–29,31–33,35–40] and animal PVs [41–43] (Figure 1). In this section, we will discuss about several methods to identify and characterize PVs genome.

Various molecular methods, such as PCR have been used to detect specific viruses or viral families. PCR can be used to detect a few copies of a particular nucleic acid, and the viral load in a sample can be quantified with real-time PCR [44].

Although many of the PCR assays investigate the presence of a specific virus, assays have been developed to detect several viruses simultaneously. The most used molecular method to study PVs through its genome is the PCR. This methodology has been widely used to detect a broad range of PVs types in human and animals. PCR-based method has been routinely used due to high sensitivity (PCR-based method can be used to detect a few copies of PVs DNA and viral load samples) and specificity [45–48].

In addition, multiple-primed rolling circle amplification (RCA) technique, hybridization, and metagenomic methods have became a convenient tool for molecular biological research on PVs [10]. Thus, the development of molecular techniques reflected advances in knowledge of PVs genomes. Particularly, viral metagenomics have provided a powerful technology to investigate the viral flora of healthy and sick human and animals [49]. By applying these methodologies to PVs studies, it is possible to gain a better understanding in the etiology of PVs, as well as deepen the knowledge into the PVs and others virus circulating in nature, such as PVs in flies, ticks, fomites and body fluids.

Also, it may provide a better understanding of the complex interaction between virus and host.

PCR-Based Methods

Nowadays, there are several molecular assays that use PCR methods for investigate PVs. These methodologies essentially differ in the PVs gene segment amplified and in the number of primers used. For clinical studies of PVs prevalence, the most frequently used primer sets are MY9/MY11, FAP59/64, and PGMY9/ PGMY11. These consensus primer sets were designed to amplify a partial sequence of highly conserved PVs L1 gene. Also, these primers are made with the use of degenerate nucleotides that increase the range of PVs detection, however, may lower its sensitivity [50]. The MY9/MY11 primer set is the most commonly method to detect HPV infection in cervical samples [51]. These primers amplify approximately 450 base pair (bp) fragments and they allow amplification of 47 HPV DNA types. The PGMY09/PGMY11 primer set is an extended version of MY09/11 primer set, which permits to increase the sensitivity to detect HPV types [52]. Alternatively, the association of fixed nucleotide primers, such as GP5+/GP6+, with degenerate nucleotide primers may be employed to increase the sensitivity to HPV.

An alternative PCR approach using primers FAP59/64 also amplify a broad spectrum of HPV types. As well as the MY09/11 primer set, the FAP59/64 primers have degenerate nucleotides and were designed to amplify a partial sequence of highly conserved PVs L1 gene [53]. The primers FAP59/64 allow the detection of 46 HPV types. Apart from HPV, FAP59/64 and MY09/11 can be used to identify a broad range of animal PVs DNA. For instance, Ogawa et al. [22] showed that MY09/11 primers allow to detect BPV1 and BPV3. Moreover, the primers FAP59/64 can detect 13 BPV types [27,28] as well as, possible putative new BPV types [22]. Furthermore, the use of FAP59/64 primers allowed to identify PVs in chimpanzees, gorillas, macaques, monkeys, lemurs, cows and elks [54].

More recently, real-time PCR has been used to detect PVs as well as viral load assessment. This method is based on the release of fluorescence at each amplification cycle, which is directly proportional to the amount of amplicon generated. With regard to Human PVs, studies have showed that real-time PCR can be used to quantify viral load, detection and genotyping in cervical lesion or cervical cancer [55–58]. Moreover, real-time PCR has been used to detect and quantify viral load of animal PV types, such as BPV1, BPV2, BPV12 [17,59–62].

Apart from the clinical importance, the use of PCR-based methods and direct sequencing allowed to demonstrate the genetic diversity within PVs. This genetic diversity of PVs DNA can occur due to synonymous and nonsynonymous mutations [35,36,63], insertions [64] and recombination [65]. These changes can alter the structure and the function of proteins and, consequently, their biological activity [66–69]. For instance, several studies have been demonstrated that variants of HPV16, HPV18, HPV31, HPV33, HPV58 and other HPV types are related to persistent infection, progression and oncogenicity [66,67,69–71]. Moreover, studies that used PCR-based method allowed demonstrating that the genetic diversity within HPV16 and HPV18 DNA co-evolved with the three major human phylogenetic branches: African, Caucasian and Asian. Therefore, the PCR-based method is an important approach used in clinical as well as evolutionary studies with regard PVs.

Although PCR-based methods have high sensitivity and specificity, this methodology presents some disadvantages, such as the necessity of specific primer to detect PVs and short amplified fragments. In contrast, multiple primed RCA method has been used to detect new PVs. The rolling circle sequence-independent amplification technique makes use of the property of circular DNA molecules such as plasmids or viral genomes replicating through a

rolling circle mechanism. Briefly, the RCA method is a DNA synthesis reaction that uses the phi29 DNA polymerase to amplify circular DNA molecules [72].

The uses of random hexamers primers, which bind at multiple locations on a circular DNA template, allow the amplification of circular DNA without requiring prior knowledge of the sequence. Recently, several studies showed the detection of new PVs using the RCA method. Although technically more demanding than other methods of sequence-independent amplification, the RCA approach has facilitated the identification of a novel PVs. For instance, the use of RCA allowed to identify 20 new HPV types in the *Betapapillomavirus* genus, 47 in *Gamma papillomavirus* genus, and 7 new HPV types in *Alphapapillomavirus* genus [13].

Similarly, RCA allowed to identify new animal PVs, such as the Canine Papillomavirus (CPV) [73,74], Feline Papillomavirus (FdPV) [75], Equine Papillomavirus (EcPV) [76], Mouse Papillomavirus (MusPV) [77], Bovine Papillomavirus (BPV) [78], *Bettongiapienicillata* Papillomavirus (BpPV) [79], *Cervuselaphus* Papillomavirus (CePV)[80] and *M. fascicularis* Papillomavirus type 1 (MfPV-1)[81].

Metagenomic Methods

As previously mentioned, several microorganisms cannot be cultivated, and therefore, some may go unnoticed and unstudied. Molecular methods widely employed such as PCR have the limitation of being used to detect specific viruses or viral families. However, metagenomics is a more general approach to study the genetic composition of uncultured samples [82]. Viral metagenomics investigates the complete genetic viral population in the sample studied [83]. These studies have also contributed to knowledge of undiscovered or low studied PVs due to its presence in no conventional sites.

In the first assays of metagenomics, the products of the amplification technologies have usually been cloned into bacteria to create libraries. Then, these cloned products were characterized by Sanger sequencing to identify any potential viruses. However, this process is quite laborious, and due to a combination of the high background of contaminating host nucleic acid and the occasionally low levels of virus, a vast number of clones may have to be sequenced before a viral sequence is identified [49]. One of these techniques, the DNase-SISPA assays includes sequence-independent amplification, cloning and sequencing of amplified viral nucleic fragments followed by in silico searches for sequence similarities to known viruses. This method requires a prior digestion of non-pathogen specific nucleic acid before viral DNA/RNA. DNase-SISPA technique have been widely used for identifying known and unknown viruses [84–86], including PVs [33].

Other independent platforms were introduced for sequencing with no need for traditional cloning after amplification and yield several hundred thousand sequence reads in one run. These techniques have different sequencing principles but all have high throughput (relative to Sanger sequencing) in common and are often referred to as next-generation sequencing or high throughput sequencing [87, 88]. For metagenomic studies, 454 sequencing is often used, mainly due to the longer read length, which makes de novo assembly easier.

Next-generation sequencing (NGS)-based metagenomic have allowed the identification of several PVs, including new PVs. Hence, the use of sequencing technologies such as the 454 sequencing platform and high throughput sequencing (metagenomic sequencing and analysis) has permitted to identify new PVs in several biological samples. With regard to Human PVs,

the use of metagenomic method identified the genomes of HPV116 in rectal swab [89] and nine putative HPV in cutaneous lesions skin [90]. Moreover, the use of this methodology seems to be important to identify PVs infection in HPV-negative samples [91] as well as sites of less common infections [92]. With regard to animal PVs, the metagenomic method allowed to identify BPV10 in teat wart of cattle [33], PVs in mosquitoes [42], a novel *Miniopterusschreibersii* Papillomavirus type 1 (MscPV1) and *Rousettusaegyptiacus* Papillomavirus type 1(RaP1) in bats [38, 93] and Tornovirus 1 (STTV1) in sea turtle [42].

Figure 1. Current methodologies used to detect Human and Animal PVs.

A MODEL FOR RESEARCH IN PAPILLOMAVIRUS: ADVANCES IN BOVINE PAPILLOMAVIRUS KNOWLEDGE

Among PVs, BPV have a major role in veterinary medicine. They can cause benign and malignant lesions in cattle and are associated with horse, zebra, buffalo, yaks, giraffes, tapirs and bison lesions [17, 26, 40, 94, 95]. BPV has been widely distributed in cattle worldwide [96]. There are reports of the presence of BPV in the Americas [28], Europe [97], Asia [98], Oceania [99] and Africa [26]. BPV is considered the etiological agent of Bovine Papillomatosis and cancers of the bladder and upper gastrointestinal tract in its natural host. Although there is no global survey on the economic impact of BPV, the numbers about world cattle population that exceeded 1 billion head of cattle reflect the importance of studying BPV. Developing countries like India, Brazil and China have the largest cattle population in the world, whereas USA, Brazil and China are the largest beef producer, respectively [100]. Cutaneous papillomas are responsible for significant economic damages to farmers due to the retarded growth of the animals, loss of weight caused by the reduction in food consumption and decrease in milk production [101,102]. Since lesions are commonly found in young animals whose immune system is still developing, its appearance is an important observation for calves because of the morbidity and mortality and high costs of treatment [103].

The presence of mucosal papillomas or tumors may progress to cancer, and the upper gastrointestinal tract and the urinary bladder are the most common locations for the development of BPV-associated carcinomas [104]. The highest economic damages caused by BPV are found in cattle from tropical and subtropical regions due to the large presence of bracken fern and its consequent chronic ingestion by the animals [104].

To date, 13 BPV types have been identified and classified into three genera: *Deltapapillomavirus* (BPV1, 2 and 13), *Epsilonpapillomavirus* (BPV5 and 8) and *Xipapillomavirus* (BPV3, 4, 6, 9, 10, 11 and 12). One BPV type is still unclassified (BPV7) [78]. All BPV types characterized so far are associated with different histopathological lesions. *Xipapillomaviruses* are pure epitheliotropic (causing true papillomas), *Deltapapillomaviruses* induce fibropapillomas and *Epsilonpapillomaviruses* can cause both types of lesions [105]. Members of *Deltapapillomavirus* genus are also associated with infections in non-epithelial sites such as blood and semen [27,106].

Besides the importance of BPV in veterinary medicine, BPV has been also largely investigated as animal model to better understand the transforming activity of PVs. BPV attracted the interest of molecular biologists since it was the first PVs able to induce transformation in cultured non-epithelial cells; furthermore its genome was the first among PVs to be completely sequenced [107]. Despite its importance, the understanding of BPV diversity is limited, probably underestimated. In contrast with HPV that presents more than 150 described HPV genomes, less than 70 non-human PVs species have been isolated and sequenced so far. However, the numbers of studies have attempted to assess the diversity and characterization of BPV genome has increased in recent years. Beyond 13 BPVs described, about 30 new putative types were isolated from various geographical regions in countries such as Brazil, Japan and Sweden. For example, BPV7, 8, 9 and 10 were designated from putative BPV types BAPV6, 2, BPV type I and BPV type II, respectively [14, 22, 54, 98, 108–111]. These studies usually employ the PCR technique with consensus primers, and as commonly these studies describe new putative types and subtypes of BPV, it is believed that there may be an underestimation of the identification of BPV types [112].

BPV are also classified into subtypes and variants, which are useful to the knowledge of biology and diversification of PVs. The differences found in nucleotide sequences of variants of PVs could be responsible for changes in the oncogenic potential, cellular location, host immune response, function of PVs proteins (affecting pathogenesis), or binding capacity of a transcription factor [5, 35, 113, 114]. A few studies related to BPV genetic variability were done. The majority of these studies were associated with equine sarcoid, aiming at understanding differences between the disease in bovine and equine [109,115].

The improvement of molecular techniques for detection of HPV allowed the discovery of these various putative new BPV types, besides the discovery of frequent multiple infections in cattle caused by various BPV types in a single skin lesion [28, 97, 116]. BPV DNA is detected by a variety of PCR-based techniques. These PCRs are based frequently on the detection of one or two BPV types using degenerated or type-specific primers. Genotyping is performed either by real-time detection [33] or by sequence analysis [117] or restriction fragment length polymorphism (RFLP) analyses [18] of the generated PCR fragments. Usually the discovery of putative new types, subtypes and variant are made in works that employs consensus primers capable of identifying potentially more than two BPV types [22]. This methodology has suggested the existence of numerous yet uncharacterized BPV types in cattle herds from diverse geographical regions. Beyond the use of consensus primers designed for HPV, such as

FAP59/FAP64 and MY09/MY11 successful in identifying cutaneous and mucosal PVs types, respectively [118,119], other consensus primers designed exclusively for L1 of BPV have been used [98].

There are reports indicating that consensus primers sometimes fail to diagnose a Papillomavirus infection because of sequence differences between consensus primers and putative PV types [54]. Beyond the use of these primers, the multiple-primed RCA technique has been applied to amplify whole genomes of PVs [120,121] and also BPV [111] and became a convenient tool for molecular biological research on PVs. Also, in cattle other sequence-independent amplification techniques like DNase-SISPA have been use for characterizing genome of BPV. Due to this plasticity, BPV genomes and BPV-like genome has been detected in several sites and hosts [27, 27, 96, 122], and metagenomic methods are very suitable for samples like plasma, serum, soft tissues, respiratory secretions, cerebrospinal fluid, urine, faeces and filterable environmental [83, 86]. Therefore, these new methods seem to be very suitable for BPV studies.

The advances in knowledge of BPV genomes and putative new genomes have been reflected by the development of molecular techniques and enabled new strategies of studies with the purpose of prevention and treatment of Papillomaviruses in cattle and other animals.

ABSTRACT

Viral particles are important tools in Molecular Biology, acting as carriers of genetic material, immunogenic antigens, adjuvants, or even directly combating antibiotic-resistant microorganisms and their biofilms in hospital and industrial environments. However, the efficient use of these particles requires extensive knowledge about their characteristics and components, including those involved in their regulatory mechanisms of genome transcription and protein synthesis. The exploration of this knowledge becomes a challenge especially for scientists analyzing the virions in their natural environment, due to their interactions with the complex and diverse types of biological systems, which directly influence the regulation of the infective cycles. Thus, knowledge about viral genes, their function, organization, and modulation, beyond the comprehension of the viral components as parts of complex systems, consist of the main hurdles for the controlled and predictable handling and use of these particles. For this, the technology of Synthetic Synthesis of viral genomes is distinguished from traditional genetic engineering through the use of modularity and standardization to construct proof-of-principle systems and allow generalized circuits designs to be applied to different scenarios. This new technology is made possible thanks to advances in many areas of science, from the use of restriction enzymes until the development of techniques of genomic synthesis and sequencing, like the 454 Roche, Illumina, and SOLiD systems. This technology is becoming increasingly a multidisciplinary tool used in the investigations about these complex systems, as well in the engineering of new particles for the optimization of diverse viral functions and

alterations in their infectivity and affinity, or even in the development of completely new organisms and features without the need for a template. Nevertheless, advances in this technology are still limited by the lack of dynamic techniques for monitoring biological systems and efficient and standardized circuits. Here, we summarize the major characteristics of viral genomes, their organization and gene modulation, and highlight the main aspects of Synthetic Biology applied to viral genomes, as its main techniques and applications.

INTRODUCTION

Viruses are infective particles essential for the balance of ecosystems and are directly related to the evolutionary processes throughout the history of life on Earth. Therefore, the study of viral genomes attracts the interest from various areas of science, since the elucidation of the genomic sequences, its function, organization and modulation are sources of important discoveries about the evolution of species and may help to explain the biological behavior of the more complex living organisms. In addition, knowledge and handling of these genomes along with techniques of molecular biology have allowed these particles be used as vectors or gene recombination agents, as antimicrobials agents helping to control microbial contamination in industries and hospitals, or still used in the production of vaccines for the control of various pathogens, for the detection of micro-organisms, among others. For example, Lu and Collins demonstrate that an engineered bacteriophage was able to enhance the killing of antibiotic-resistant and biofilm-former bacteria, and act as a strong adjuvant for other bactericidal antibiotics (T K Lu & J J Collins 2007).

Viral genomes are extremely variable in size and structure of genes, but patterns can be observed along the evolutionary studies, especially among closely related viruses. The techniques for sequencing these genomes are already a practice and economic reality, allowing the study of genes, their function and modulation for handling these genomes can be accomplished in a rational and predictable way. Accordingly, the chemical synthesis of genes has been gradually made possible, but yet is not a reality in terms of genomes, and biological techniques are still necessary for the union of synthetically synthesized chains of nucleotides. The scientific community's interest in this issue is so meaningful that in 2012 was created a journal exclusive for this theme in which researchers could report the successful cases in the study and manipulation of viral genomes.

In this chapter we discuss about the main elements of the viral genomes, as well as modern techniques for sequencing and manipulating these genomes, concluding with an approach about the concepts of synthetic biology and examples of success in the synthesis of synthetic viral genomes reported throughout the world.

ESSENTIAL ELEMENTS OF VIRAL GENOMES

Essential Genes

In the cells and viral particles, the constancy of genetic networks form biological networks, which act synergistically to perform various metabolic functions (Figure 1) (Riccione et al.

2012). Thus, a major goal of Cellular Biology is to understand how these complex networks culminate in the observed cellular behaviors. One of the most used method to assess a gene function or genetic network is based on the isolation of mutants unable to complete a particular pathway. The mutations in the viral genomes can interfere with a range of properties of these particles such as infectivity, the type of lysis plaque formed by them, their host range, or the physicochemical properties of the particles. However, the production of lethal mutations generates unviable virions, thus making them undetectable. Strategies based on synthetic biology to study genetic circuits or viral motifs gene can be a solution to this problem. Thus, to obtain more complex circuitry is necessary to know which genes confer essential characteristics to each organism, which has led to a large number of studies devoted to this subject (Little 2010).

Figure 1. The more complex circuits have various integrated routes. Synthetic biology allows reconstructing parts of these circuits with different purposes, such as the study of these genes, the production of metabolites and control of cell populations (adapted from Riccione et al. 2012).

Viruses have high genetic diversity, ranging from extremely simple genomes, such as that of porcine circovirus, which has a circular genome of only 1.7 nucleotides and three Open Reading Frames (ORFs) (Figure 2), till extremely large genomes, such that of mimivirus, which genome codes for more than 900 ORFs (Abrescia et al. 2012). There is not a universally conserved gene among all viruses. However, some genes that encode proteins required for replication and particle formation are present in all members in a group (Dolja & Koonin 2011). Although there is similarity between sequences of the viral genomes analyzed until now, surprisingly the vast majority of sequences of viruses present in ocean has low similarity to known viral sequences, finding greater similarity to bacterial genes, some involved in the main processes of the cellular metabolism. Two not mutually exclusive hypotheses could explain this issue, one based in the contamination of samples with bacterial DNA, raising the possibility of fails in that protocols of metagenomic analysis, and the other in the fact that our current knowledge on viral genomes is not representative of the current virome which makes oceans the main viromes on the planet (Kristensen et al. 2010).

Figure 2. Genomes with different degrees of complexity. A) PCV genome, the simplest viral genome known, composed of essential genes for replication (ORF1), virion assembly (ORF2) and host apoptosis (ORF3). B) UFV-P2 genome, with intermediate complexity and at least two transcription modules of replication and virion assembly and release. C) mimivirus genome presenting high complexity, possessing 1.2 Mb and more than 900 genes (Raoult et al. 2004).

Due to the great diversity of viral genomes and the distinct genetic needs between different viruses, there are no genes that are essential to all of them. However, two proteins are considered the minimum requirements for the existence of a viral particle - the viral capsid protein and - the viral polymerase. Although the genes encoding these proteins are highly variable among different groups, its existence is almost unanimous among known viral genomes. The other genes present in the viral genomes are components of transcription modules that vary between different virus groups and depend on the particle structure and their mechanism of infection/replication. Next are cited groups of some viruses and their basic replication machinery.

1. Bacteriophages as well as plasmids, can be considered genetic elements, motile or not, present in prokaryotic cells. Once internalized, the genomes of these viruses are called prophages or replicons, and replicate intracellularly by the "replicon model" using key regulatory elements that interact with an origin of replication (Ori). The replication of linear viral genomes composed of dsDNA seems to be simple, despite its unidirectional mechanism of initiation, which leads to the loss of a portion of the genome in each replication cycle. Evolutionary studies showed that phages found at least four different mechanisms to address this issue: 1 - The *Bacillus subtilis* phage Φ 29 proteins uses specific proteins as portable primers, which remain covalently attached to the ends of the viral genome; 2 - The *Escherichia coli* phage T7 possess direct repeats at the terminal ends of its genome, which are regenerated by the processing of its concatamers by enzymes called terminases during the packing of monomeric genomes, 3 - The *Escherichia coli* phage N15 regenerates the ends of its linear double-stranded DNA by the action of the specialized enzyme protelomerase, similarly to what happens for eukaryotic genomes by the enzyme telomerase, 4 - linear genomes of some phages are circularized after its injection into the host, while others are integrated into the host chromosome in the form of prophage.
2. The porcine circovirus (PCV) are small, icosahedral viruses with approximately 17 nm in diameter and composed of a circular ssDNA genome. Replication of the genome of PCV-1 is made by rolling circle (RCR) mechanism, which is widely used by phages, plasmids, animal viruses and phytoviruses (Cheung 2012). The PCV have two opposing ORFs from the Ori region. The ORF1 is transcribed and processed, giving rise to the Rep proteins (Rep and Rep[']) related to viral replication. ORF2 is present in the complementary strand and is responsible for the synthesis of the viral capsid protein (Cheung 2012). The ORF3 was recently characterized as a non-structural protein, not essential for replication in cell cultures, and with a major role in the induction of apoptosis by activating the initiation of the via of caspase 8 and caspase 3 in the host (Liu et al. 2005).
3. Viruses of the *Flaviviridae* family have linear genomes consisting of single stranded RNA (ssRNA) with positive polarity, what means that it can be transcribed immediately after its entry into the host cell. These genomes are transcribed as a single polyprotein, which is cleaved generating the viral structural and non-structural proteins. Among these is the NS5 protein, a RNA-dependent RNA polymerase (RdRp), which is essential for the phage genome replication, since natural animal cells do not possess this enzyme. A second element essential to the replication of these viruses is the sequences for cyclization, present in the terminal ends of their genomes.

Recent studies show that the RdRp binds to the clamp formed after genome circularization and initiates its replication by synthesizing the negative strand RNA, which is the replicative intermediate of flaviviruses (Malet et al. 2008).

4. Until the discovery of mimiviruses, the concept of viruses was based on the filtration of solutions in membranes with 500 nm pores. However, mimivirus have a diameter of about 750 nm, beyond fibrils, which made this definition improper. Although little is known about the different stages of mimiviruses infection, it is known that their 981 genes characterize them as the first known viruses with complex genomes similar to other intracellular bacterial parasites. In addition, these viruses were the first in which components of the system of protein synthesis were observed, such as amino-acyl tRNA synthetases (Claverie & Abergel 2010). In addition to size and complexity of its genome, the mimivirus are characterized by a high gene density (90.5%), with something like 1262 ORFs, and of these 298 have function assigned to several central functions of cellular metabolism, ranging from the amino acid metabolism and transport, translation and post-translational modifications.

Organization and Modulation of Viral Genomes

The evolution of the viral particles led to the mobile interchangeable elements, known as modules, which carry specific biological functions. Thereby, viruses found ways to adapt their genomes to different niches through the combination of different modules. A detailed comparison of two genomes from phages belonging to different niches may shows similarities in genetic organization, although containing alternating regions of high and low sequence similarity (Botstein 1980). The high degree of conservation in the ordering of functional genes into transcriptional modules is evident, allowing the inference of functional proteins by comparing the gene sequences using bioinformatics (Veesler & Cambillau 2011). Furthermore, the homology in the organization of modules in phages from different families enables the establishment of hybrids between them.

The genetic modules have two basic characteristics: the efficient conducting of their biological functions and their ability to permute among genomes. Both features define the frequency at which each module is inserted (or lost) in a genome, and this decision is mainly related to the functional compatibility of a module with a variety of combinations with the other essential modules present in the genome of an organism. Thus, the presence/absence of specific viral modules in the genomes may be also indicative of the phylogenetic distance of viral hosts. Lawrence and coworkers proposed that the prophages and phage genomes could be described as an assembly of several genetic modules, which tend to remain associated independently of the recombinant nature of their genomes (Lawrence et al. 2002). Therefore, these modules can be classified according to the functions of their inner genes, as occurs in the modules of adsorption, replication, regulation, recombination, capsid, basal plate, proteins forming contractile tails, proteins forming long non-contractile tails, tail fibers, lysis, integration, excision and pathogenesis (Toussaint et al. 2007; Lima-Mendez et al. 2011).

The classification of viruses can be performed by the analysis of evolutionarily conserved modules (ECM). Some ECMs appear to be specific to certain types of phages, host groups, or type of infective cycle. For example, the ECM17 is composed of two sub-modules, the first of integration/regulation, which are real markers for integrative phages, and the replicative module

found in Gram-positive-infecting phages (Pellegrini et al. 1999; Lima-Mendez et al. 2011). Recently, a software was developed based on this type of classification and was named Phage Classification Tool Set - PHACTS, which uses genomic analysis to predict the infective cycle of different phages (McNair et al. 2012).

METHODOLOGIES FOR GENOMIC MANIPULATION

The term Synthetic Biology was first described in 1910, by Leduc, S. (Stéphane Leduc 1910). This technology has enabled the development of cells and biological devices with features molded according to a number of different interests. This has led to a demand for more dynamic, simple, and cost effective new technologies of DNA synthesis and sequencing (T K Lu & J J Collins 2007).

Genomic Sequencing

The first regulatory circuits were discovered over 40 years and consisted of a feedback inhibitors of amino acidic biosynthetic pathways (Westerhoff & Palsson 2004). The discovery, production and commercial viability of restriction enzymes, and the standardization of techniques as molecular cloning constituted major advances in the 70s, allowing the emergence of technologies such as Genetic Engineering and Biotechnology. Already in the 1980s some of the fundamental experimental approaches of Molecular Biology were developed and improved, and in the mid 90's the first automated DNA sequencers were glimpsed, leading the genetic sequencing to the genomic scale. The automation, miniaturization and multiplexing of multiple trials led to the generation of additional types of "omic" data, such as metabolomics, proteomics, and genomics (Westerhoff & Palsson 2004; Hunkapiller et al. 1991; Rowen et al. 1997; Uetz et al. 2000).

The first methodology for sequencing DNA was the chemical method of *Sanger*, in which labeled modified nucleotides are used for reading the template DNA during amplification. The Human Genome Project was performed by a variation of this method, the *shotgun sequencing*, in which the DNA is mechanically or enzymatically broken and the fragments generated are cloned and individually sequenced. After obtaining individual sequences, these are then overlapped for the assembly of the entire genome. The new sequencing methodologies known as next generation sequencing (NGS) are based on this principle, performing random reads throughout the genome and assembling the fragments generated by overlapping (J. Zhang et al. 2011). However, the number of bases that can be continuously read by NGS methods is very small when compared to Sanger, what is the major limitation of these methods since they generate a very large amount of data, making their processing difficult and time-consuming. Some of these new platforms are described below:

1. Roche GS-FLX 454 – It was as the first commercial sequencing platform, introduced in 2004, and has as main advantage the generation of the larger fragments among the NGS platforms. The key process is based on mixing the reactants for amplification in an emulsion. Inside the micelles, the amplification is performed in DNA-binding

beads. In this platform, the DNA is read through pyrosequencing, in which light is emitted and recorded when each nucleotide is incorporated by the polymerase during the fragment amplification.

2. Illumina - It was the second platform to be commercialized and is currently the most used due to its lower costs. This platform is also based on the sequencing by synthesis, in which DNA fragments are attached to fixed supports via adapters (oligo-primed). These oligo-adapters are also used to amplify the free end of the DNA fragment, thus generating clusters of identical fragments. The amplifications using terminators nucleotides labeled generate signals that are interpreted and give rise to the sequence of each fragment.
3. SOLiD - This platform is based on sequencing by ligation, in which the templates are attached to microspheres in emulsions and combined with universal sequencing primer, the enzyme ligase, and fluorescent probes. Sequencing occurs by hybridization of such fluorescent probes with the target fragment through several steps using different combinations of universal primers.

In the last two years new genetic sequencing platforms were presented and called third generation sequencing. One of them is based on changes in electric current generated by the passage of DNA in nanopores, with an ability to read million bases per hour. A second method is based on the variation of electrical conductance of a solution, which occurs due to the polymerase addition of nucleotides to the chain of nucleic acids, presenting processivity about 22 nucleotides per second (Y. S. Chen et al. 2013; Radford et al. 2012; Eisenstein 2012).

Genetic Manipulations

The mutations in the phage genomes may be obtained from the use of physical agents such as ultraviolet light, chemical mutagens, or by recombinant DNA technology. These techniques allow changing specifically or randomly the sequences of nucleotides that compose the viral genomes, thus generating particles with different characteristics in relation to the wild ones. For example, the technique of *DNA shuffling* allows the random recombination of fragments between homologous genes, thereby generating a series of particles with different versions of a particular gene. On the other hand, *error prone PCR* is a technique of inducing errors during amplification of a specific gene, generating directed punctual mutations. Homologous recombination has also been used for deleting genes or obtaining recombinant phages. The technology known as *recombineering* allows the introduction of *in vivo* changes, such as knock outs, deletions, insertions, or point mutations, in a genome. Yu and coworkers reported the development of a transformation system of *Escherichia coli* genome by inserting the recombination system of the phage λ (Exo and Beta) in the recombination system *RecBCD* (Marinelli et al. 2012; Yu et al. 2000).

The chemical synthesis of nucleotide sequences led to a race of biotechnology companies for more efficient ways to synthesize genetic material with increasing amounts of nucleotides, making it possible to sell affordable gene sequences. Currently, it is possible to a researcher to purchase gene sequences as large as 10,000 base pairs with a delivery time of about a month! The high-throughput DNA synthesis technology provides to researchers a new and important tool. However, the big question still lies in correctly performing the biological question to be

answered by this tool, which can be facilitated by detailed study and mathematical modeling of the known genetic circuits. The chemical modification of nucleotides and the generation and study of isolated circuits offer a way to study independently the influence of circuits in natural pathways without disturbing the other components of the metabolism.

Some of these circuits have been used in useful tasks, such as control of cell populations, decision making for biosensors, genetic timer for fermentation processes, and image processing. More recently these circuits have been used to solve medical and industrial solutions such as for the development of bacteria capable of invading cancer cells, for the dispersion of bacterial biofilms by engineered phages, as well as for the production of precursors of anti-malarial drugs for the generation of synthetic microbial routes. However, in such cases, engineered organisms have a single modified gene circuit, which does not include the potential offered by synthetic biology, so showing a discrepancy between the simplicity of these genetic circuits and the promise of assembly of these circuits in complex genetic networks (T K Lu et al. 2009). Although there are no limitations on the number of new circuits to be built, the number of interoperable and well-characterized parts hampers the development of more complex biological systems, thus creating a constant need to expand the set of available tools. This limits our ability to build truly modular circuits and highlights the need for an accurate characterization of the interactions between the different components of these systems so that negative interactions are minimized (T K Lu et al. 2009).

SYNTHESIS OF NEW VIRAL GENOMES

The beginning of the study and synthesis of genetic circuits evolved the manipulation of the genetic material of most organisms by a series of restriction enzymes, recombination and amplification reactions, and the expression of heterologous proteins in foreign systems. While these techniques are now used routinely in laboratories around the world, the need for templates for genetic manipulation and the high complexity of the regulatory system of the host led to the need to synthesize *de novo* genomes, from which it would be possible to predict the interactions between different genetic components. Thus, the chemical synthesis of long polymer chains of nucleotides and the construction and maintenance of DNA libraries have favored the emergence of this new way of creating and manipulating entirely new biological systems.

The synthesis and manipulation of genes for their insertion or deletion in the genomes is already a strategy routinely used in different fields of science, for example, in elucidating metabolic pathways, in discovering gene function, or to genetic improvement. However, the synthesis of new genomes without templates has been done only since the last decade, and the increasing knowledge on the functions of regulatory sequences have contributed to the synthesis of larger and more complex genomes, with increasingly predictable and rational designs. An example was the synthesis *de novo* of a bacterial genome in 2010 (Gibson et al. 2010). While the synthesis of genes considered natural and proximal regulatory aspects, the genomic synthesis should consider the different regulatory elements contained in the entire genome, the interactions between them, and the products of the different genes. This is only possible from a consolidated knowledge about the viral genomes, its function and modulation.

Genetic Circuits

Synthetic biology integrates the techniques of molecular biology to the principles of engineering, computer sciences, and mathematical models. From this integration, it is possible to design and construct genetic circuits that enable living cells to perform new functions. The term genetic circuitry has been widely used to refer to well-defined sequences of genetic material that, together, perform specific functions when transcribed. This concept is directly related to the rational construction of genomes with predefined characteristics. A large number of genetic circuits have been developed, most of them switches, oscillators, digital logic gates, filters, modular and interoperable memory devices, counters, sensors and protein scaffolds (Timothy K Lu 2010). By using these circuits is possible to predict, at least partially, the features and biological modulations of synthetic viral particles, which can be manipulated to present characteristics desirable in relation to the functions for which they are used. In the future, researchers envision that, by analogy to electronic circuits, it will be possible to generate viral particles programmable from the generic combination of genetic circuits which, when combined, generate an predictable phenotype (Ferber 2004). For this, it is necessary to develop well-defined stages of construction, monitoring and debugging and setting of these circuits.

Monitoring the Expression of Genetic Elements

Practices methodologies of large-scale monitoring of the expression of circuits are essential for the development of efficient networks and for obtaining reliable and reproducible results. These techniques are mainly based on the detection of reporter elements - molecules whose concentration is proportional to the expression of the target gene, as mRNAs and proteins. there are many methods based on this concept, but the optimal methodology for monitoring gene circuits, although it is dependent on the circuit involved, may generate strong signals with low noise, present specificity, low cost, non-invasiveness, multiplexability, and, if possible, generate dynamic real-time signals (Timothy K Lu 2010). It is possible to monitor a circuit for analyzing the total protein content of an organism without the need for a reporter element. However, this method is nonspecific and often non- accepted for the quantitative determination of expression, and thus does not significantly contribute to the understanding of these circuits. Thus, some macromolecules are frequently used as reference detectors agents. Initial studies relied on the determination of the promoter activity by the simple fusion of the promoter plus the gene of interest with a particular reporter gene. These systems are very effective and used in a number of systems, although the scientists still search for alternatives that are less invasive, cheaper and applicable to a larger number of systems.

Colorimetric Assays

The colorimetric assays for monitoring protein expression consist of simple but inaccurate techniques. These assays are based mainly on the co-expression of the gene of interest with an auxiliary gene encoding a colored product, or an enzyme capable of generating products detectable in visible light and therefore measurable. For example, one of the first systems used for reporter gene expression was based on colorimetric assays involving the enzyme β -galactosidase (β -gal) encoded by the gene *lacZ* in the lac operon in *Escherichia coli*. Cleavage

of galactosidic substrates by this enzyme generates colored products whose concentration can be measured in a spectrophotometer and is proportional to the amount of enzyme. Thus, the expression of the genes of interest under the promoter of the lac operon can be tracked by monitoring the expression of the β -gal gene. Advantages of this method include its simplicity and low cost, in addition to the vast knowledge about the parameters that could influence the results. Among the main disadvantages are sharing of a promoter, low precision and low reproducibility.

Green Fluorescent Protein (GFP)

The production and detection of fluorescent proteins is already a practical and well characterized technology for sensing and monitoring protein expression of genetic circuits. Furthermore, this technology is not specific and can be applied to a variety of circuits. The cloning of the GFP gene from jellyfish (*Aequorea victoria*) in heterologous systems allows monitoring of its expression via the emission of green fluorescence by the protein after excitation by blue or UV light. For this, scientists couple the gene coding for this protein to the gene of interest using an expression systems and, thus, are able to quantify it and even to locate it in various systems. However, because it is a protein, intrinsic and extrinsic factors involved in its stability, conformation and interactions with various components of the cell may interfere with the accuracy of the methodology. The main advantage of using this protein is the possibility of in vivo and in real time monitoring, without the need for extraction steps or destruction of the particle.

Luminescence

The systems for monitoring protein expression via luminescence emission are based on exothermic reactions that emit luminescence. The main example is undoubtedly those that uses the enzyme luciferase expressed by the *luc* gene, cloned from the genome of firefly (*Photinus pyralis*). This enzyme catalyzes the oxidation of luciferin in the presence of ATP, Mg^{2+} and O_2 , generating a light signal that is proportional to the amount of the enzyme. Systems based on luminescence present high sensitivity, speed and are relatively inexpensive. However, in the same way using GFPs, the results depend on the efficiency of the maintenance of the enzymatic activity by stabilizing the system conditions. Specifically, these system also present a great sensitivity to variations in ATP concentrations, which can make their use unfeasible in some cases.

Aptamers

Aptamers are fragments of macromolecules, specially nucleic acids, that are capable of specifically recognizing and detecting proteins. However, their in vivo use has not been widely applied to the monitoring of genetic circuits because the algorithms that could safely predict the binding affinity between aptamers and the proteins of interest would be extremely specific and therefore not viable, since they are not applied to different cases. However, alternatives that use these molecules also can be developed for detection of proteins in several different systems.

Detection of Cellular mRNAs

The amplification of the mRNA for quantitation of the expression of certain genes constitutes a simple and well-characterized technique for monitoring the expression of genes contained in genetic circuits and governed by different modulators. However, besides not being an accurate picture of the protein content of the host, thus excluding the translational stages, techniques for detecting nucleic acids require the extraction of this material and consequently the destruction of the cells analyzed. This is therefore an invasive technique and impractical for real time analyses. The detection of RNAs by fluorescent proteic probes can be an alternative to these issues, but requires that the RNA of interest are modified so that it can specifically bind to the probe.

Debugging

The number of genetic circuits that have presented unexpected results is still very high. This is due to our still limited knowledge about the different parameters involving biological circuits for the synthesis of viral genomes, and the interactions between the components of these circuits and the machinery of the host. In addition, living organisms do not respond linearly according to its components due to the co-operability between molecules, which makes even more challenging to develop predictive mathematical models for these systems. The debugging of genetic circuits involves the detailed characterization of these systems, all available nodes, modifications by trial and error to characterize the interactions between the molecules involved, and specific modeling.

EXAMPLES OF PROJECTS ON SYNTHETIC GENOMES

1. *Bacterial gene circuits*: In 2004, the group of researchers leaded by Hideki Kobayashi and colleagues engineered genetic circuits coupled to the cellular machinery of an *E. coli* strain. For this, they inserted plasmids containing a gene essential for biofilm formation under the control of a repressor regulated by RecA protein, which is responsible for mediating the SOS response. The circuit designed was capable of responding to biological signals (damage to genomic DNA) in a predictable and programmable way, so that cells formed biofilm when stimulated. With this, the researchers showed that the genetic circuits can be used to program bacterial cells, through coupling these circuits to the interactions networks of the cell itself (Kobayashi et al. 2004).
2. *Synthetic viral genomes*: Aiming the degradation of bacterial biofilms, American researchers engineered the genome of bacteriophage T7, an *E. coli*-specific phage, in which they inserted the gene for the enzyme dispersin B, which is able to reduce biofilms of different species of bacteria. The gene was inserted under the control of the T7phi10 promoter, so that the enzyme was expressed during infection of the phage and thus released after bacterial lysis. The engineered phage was about two orders of magnitude more efficient in degrading the biofilm matrix as compared to the wild phage (T K Lu & J J Collins 2007).

3. *Synthetic viral genomes*: using tools of synthetic biology, Paul R. Jaschke and colleagues recently published a study aiming establish methods enabling the synthesis, assembly, and recovery of a bacteriophage genome via yeast. They used the bacteriophage øX174 given its small circular genome with 5386 nucleotides that codes 11 gene products with overlapping open reading frames. The researchers questioned whether this overlap was essential or might be eliminated. For this, they synthesized a 6302 nucleotide synthetic genome separating all ORFs and their regions of translational control. The synthesis of the synthetic genome was performed by a combination of two different strategies: chemical synthesis and PCR amplification. For the synthetic genome was reduced to the exact size of the wild genome, the F gene, which encodes the coat protein, was truncated. The researchers were able to recover infective virions containing the truncated and decompressed genome from replication cycles in *E. coli* expressing the F gene under an inducible promoter. These results indicate that the overlap of genes in the genome of this phage is probably just a tool for genome compaction to facilitate its packaging into the viral particles, but is not necessary for the virions viability (Jaschke et al. 2012).

PROSPECTS

Although gene manipulation and processing of viral genomes are already routinely used in laboratories for the modification of viral characteristics, the development of entirely new synthetic genomes without the use of templates and considering the genetic circuits as an unit for assembly of genomes, comprises a new theme and is still relatively obscure. The hurdles to predict and forecast the synergistic behavior of these circuits lead to security issues that must be answered before this method becomes popular. This only will be possible from the knowledge on the interactions between the different components of this circuit, and the monitoring and debugging of the already created circuits in order to increase the existing mathematical models and algorithms to optimize the predictability of these systems. Even so, the creation of entirely new viral genomes is considered one of the most promising technologies for the development of new methods of genetic transfer and recombination, for the generation of new more specific and efficient antimicrobials, for the planning of new vaccines and specific antiviral drugs with lower side effects, and also for the detection of microorganisms in various industrial and hospital environments, where strict control of the microbial population is essential.

CONFLICT OF INTEREST

None of the authors of this paper has a financial or personal relationship with other people or organizations that could inappropriately influence or bias the content of this chapter.

ABSTRACT

With increase of microbial and viral genome sequence data obtained from high-throughput DNA sequencers, novel tools are needed for comprehensive analyses of the big sequences data. An unsupervised neural network algorithm, Self-Organizing Map (SOM), is an effective tool for clustering and visualizing high-dimensional complex data on a single map. We previously modified the conventional SOM for genome informatics on the basis of batch-learning SOM (BLSOM), by making the learning process and resulting map independent of the order of data input. Influenza virus is one of zoonotic viruses and shows clear host tropism. Important issues for bioinformatics studies of influenza viruses are prediction of genomic sequence changes in the near future and surveillance of potentially hazardous strains.

To characterize sequence changes of influenza virus genomes after invasion into humans from other animal hosts and to study molecular evolutionary processes of their host adaptation, we have constructed BLSOMs for oligonucleotide, codon, amino-acid, and peptide compositions in all genome sequences of influenza A and B viruses and found clear host-dependent clustering (self-organization) of the sequences.

Viruses isolated from humans and birds differ in mononucleotide composition from each other. In addition, host-dependent oligonucleotide and peptide compositions that

* Corresponding Author's Email: takaabe@ie.niigata-u.ac.jp.

cannot be explained with the host-dependent mononucleotide composition are revealed by these BLSOMs. Retrospective time-dependent directional changes of oligonucleotide compositions, which are visualized for human strains on BLSOMs, can provide predictive information about sequence changes of the newly invaded viruses from other animal sources.

Basing on this host-dependent oligonucleotide composition, we have proposed a strategy for prediction of directional changes of virus sequences and for surveillance of potentially hazardous strains when introduced into human populations from nonhuman sources. Millions of genomic sequences from infectious microbes and viruses will become available in the near future because of their medical importance, and BLSOM can characterize such big data easily and support efficient knowledge discovery.

INTRODUCTION

Due to the revolutionized advancement of decoding the genome sequences, their data have been growing into supermassive “big data” in the International DNA Data Banks, and therefore, large-scale data mining have become vital. The more the available information becomes larger, the more the rightfulness of the proposed model will become verifiable as long as the model is appropriate. At the same time, because of massive amounts of data available, analyzing only a limited part of the data should lead to an image of “the authors may have made convenient stories by extracting useful data for them”, especially when a novel discovery is publicized. It should be important to have a stance “all data belonging to a certain category have to be analyzed, even if the amount of the data is very large”. Therefore, in the post-genome era, the research that gets the picture of the whole will become increasingly important and the present chapter introduces a bioinformatics method suitable for this type of a large-scale analysis.

In more detail, we introduce the studies to unveil the species-specific characteristics in the genome sequences by using “BLSOM” developed by our group [1, 2]. This BLSOM for oligonucleotide composition has been developed for genome informatics, on the basis of SOM (Self-Organization Map) originally established by Kohonen and his colleagues [3, 4]. Because BLSOM can analyze millions of sequences simultaneously, almost all known genome sequences have been clustered and analyzable on a single map [5].

GC% has been used for a long period as a fundamental parameter for phylogenetic classification of microbial genomes, including viral genomes, but the GC% is apparently too simple a parameter to differentiate a wide variety of microbial genomes. Oligonucleotide composition, on the other hand, can be used to distinguish the species even with the same GC%, because the oligonucleotide composition varies significantly among the genomes and is called ‘genome signature’ [6]. Previously, we have constructed BLSOMs for di-, tri-, or tetranucleotide composition in all genomic fragments (e.g., 10, 50 and 100 kb) derived from a wide range of prokaryotic and eukaryotic species and found that, without giving any information of species, most of the fragment sequence have been separated (self-organized) according to species [1, 2, 5].

Epidemics of influenza viruses have been frequently repeated among various animal species including birds and swine besides human. Given that the strains derived from nonhuman sources are also capable of infecting humans, it should be impossible to eradicate influenza viruses from the planet. Influenza virus has developed into a pandemic among humans at least four times (in 1918, 1957, 1968 and 2009), causing considerable damages.

Virus requires many host factors (e.g., nucleotide, amino acid and tRNA pools and host proteins) when it grows; therefore, it inescapably depends on new host factors when causing a new infection to humans from other animal species. In such cases, the genome sequence of the virus will change to fit the new cellular environments including various host factors. If this view is correct, influenza viruses are likely to modify some part of the characteristics of their genome sequences depending on host, during epidemics in a new host. In other words, it enables us to predict, at least in part, the direction of sequence changes in the newly invaded virus, if we can properly find out the host-dependent characteristics of viral genome sequences. In this chapter we introduce examples of analysis on the host-dependent characteristics of influenza virus genome sequences, which is a key to conduct forecasting their sequence changes after changing hosts. In the previous study, we have attempted BLSOM analyses on viral genome sequences all available in that time [7]. Here, we introduce the BLSOM analysis, which includes the newly accumulated sequences and examine whether the directional changes proposed in the previous paper is actually observed in the sequences obtained after our previous paper. This type of confirmatory studies should be important to verify a novel bioinformatics method.

MATERIALS AND METHODS

Viral Genome Sequences

A total of 856,730 virus sequences analyzed in Figure 1 were obtained from the NCBI and a total of 12,370 influenza A and B virus strains analyzed in Figure 2 were obtained from the NCBI Influenza Virus Resource (<http://www.ncbi.nlm.nih.gov/genomes/FLU/>) [8].

Batch-Learning Self-Organizing Map (BLSOM)

SOM is an unsupervised neural network algorithm that implements a characteristic non-linear projection from the high-dimensional space of input data onto a two-dimensional plane [3, 4]. We modified the conventional SOM for genome informatics to make the learning process and resulting map independent of the order of data input on a basis of Batch-Learning SOM: BLSOM [1, 2, 9]. The initial weight vectors were defined by principal component analysis instead of random values. BLSOM learning for oligonucleotide composition was conducted as described previously [1,2]. BLSOM learning for synonymous codon usage and visualization of diagnostic codons for the category separation were conducted as described by Kanaya et al. [9]. BLSOM program was obtained from UNTROD, Inc. (y_wada@nagahama-i-bio.ac.jp).

Oligonucleotide composition is normalized for the sequence length and the normalized composition is used for BLSOM calculation. Mono-, di- or tri-amino acid composition in eight genes of influenza virus strains is calculated, and those of eight genes are summed up for each strain. The composition normalized with a total length is used for BLSOM calculation.

RESULT

Oligonucleotide BLSOM for All Virus Genome Sequences

To explain the clustering powers of BLSOM for a large number of genome sequences from a wide variety of viruses, we have initially constructed BLSOM for di- and trinucleotide composition in all viral genome sequences currently available (ca. 860,000 sequences), which have been classified into 67 phylogenetic families (Figure 1). Lattice points that contain sequences from one phylogenetic family are indicated in color, and those that include sequences from more than one family are indicated in black. A major portion is colored, which shows that a major portion of sequences is classified (self-organized) according to phylogenetic family; 95 and 98% of viral sequences are located in colored lattice points on di- and tri-BLSOMs, respectively. Notably, no information in regard to phylotype has been given during the BLSOM calculation. It should also be mentioned that approximately one million sequences are analyzed simultaneously on one plane.

Figure 1. Oligonucleotide-BLSOMs for virus genome sequences. BLSOM has been constructed for di- or trinucleotide composition (Di or Tri) in 856,730 viral genome sequences. Lattice points that include sequences from more than one phylogenetic family are indicated in black, and those containing sequences from a single phylotype are indicated in a color representing the phylotype: Arteriviridae (■), Bunyaviridae (■), Coronaviridae (■), Flaviviridae (■), Geminiviridae (■), Hepadnaviridae (■), Herpesviridae (■), Orthomyxoviridae (■), Paramyxoviridae (■), Picornaviridae (■), Potyviridae (■), Reoviridae (■), Retroviridae (■), Rhabdoviridae (■) and others (various colors not specified here).

Oligonucleotide BLSOM for Influenza Virus Genomes

Over ten thousand genome sequences of influenza A and B virus strains are registered in the International Nucleotide Sequence Databases, even when we concern strains for which all eight segments have been sequenced. We have next constructed a tetranucleotide BLSOM for all influenza A or B strains registered in Influenza Virus Resource [8] in NCBI (Figure 2); for di- and trinucleotide BLSOMs, refer to our previous paper [7]. Because the direct target of natural selection is a virion containing a full set of eight genome segments, tetranucleotide frequencies in the eight segments are summed up for each strain and BLSOM is constructed with the summed frequency after normalization of a total nucleotide length of individual strains; this is because the length of genome sequences compiled by the Influenza Virus Resource differs slightly between strains (Figure 2). The present genome-level analysis should provide valuable information for characterizing individual strains, which may not be obtained by a

gene-level analysis, primarily conducted with sequence homology searches used in phylogenetic tree analyses.

Figure 2. Tetranucleotide-BLSOM for influenza A and B virus genome sequences. (A) Tetranucleotide BLSOM (Tetra) has been constructed for 12,370 strains of influenza A and B virus strains. Lattice points containing sequences from strains isolated from more than one host are indicated in black, and those containing sequences from one host are indicated in a color: avian, red; human, green; swine, blue; equine, yellow; bat, grey; and influenza B strain, light blue. (B) Human subtype. On the tetra-BLSOM presented in (A), each human virus subtype is specified in a color: H1N1, light blue; H1N1/09, dark green; H3N2, blue; H5N1, red; H7 and H9, pink; and other human subtype, green. (C) Occurrence levels of tetranucleotides, which are diagnostic for host-dependent clustering, are indicated with different levels of two colors: pink (high), green (low), and achromatic (intermediate) as described by Abe et al. [1].

Lattice points containing virus strains isolated from one host species are indicated in a color representing the host and those containing strains isolated from more than one host are in black. Though only oligonucleotide frequencies have been given during the BLSOM calculation, viral sequences are clustered (self-organized) according to host. Viruses are inevitably dependent on many host factors for their growth (e.g., pools of nucleotides, amino acids and tRNAs) and at the same time have to escape from antiviral host mechanisms such as antibodies, cytotoxic T cells, interferons, and RNA interferences [10-13]. Host-dependent clustering of viral sequences visualized on BLSOM should reflect this host dependency in their growth.

In Figure 2B (Human Subtype), lattice points that contain human influenza A viruses of one subtype on the tetra-BLSOM (Figure 2A) are specified with one color representing the subtype. Among the 12,000 viral strains analyzed, approximately 3,000 strains correspond to the new pandemic H1N1 strain (H1N1/09) (dark green in Figure 2B), which has started its pandemics among humans around since April 2009. Although its origin is derived from avian strains, it has been infected to human via swine after genome segment reassortments. Interestingly, on BLSOM, they are located apart from seasonal human H1N1 or H3N2 strains (light blue or dark blue in Figure 2B) and surrounded by avian and swine territories (red and blue in Figure 2A and blank in Figure 2B). It can be possible that these H1N1/09 strains have not yet been best suited to growth under human cellular environments.

We next investigate human virus subtypes other than the H1N1/09 (Figure 2B). Human seasonal H1N1 and H3N2 are clearly separated from each other; light and dark blue in Figure 2B. In addition, in contrast to H1N1/09 (dark green), human H5N1 strains (red in Figure 2B and mainly black in Figure 2A) are rather scattered within the avian territory (red in Figure 2A

and blank in Figure 2B). This should show that the human H5N1 strains have jumped to humans but are not able to spread from human to human [12], and therefore, they have characteristics of avian viruses. These human H5N1 strains are more separated from the swine and human territories than H1N1/09 strains, and this difference may relate to their infection power in the human and swine populations.

In the case of influenza B strains (light blue in Figure 2A and blank in Figure 2B), which have repeatedly caused epidemics only among humans, they form a territory more distant from the avian territory than that of human seasonal strains. This characteristic of influenza B strains will be discussed later.

Diagnostic Tetranucleotides Responsible for Host-Dependent Separation

BLSOM provides a powerful ability to visualize diagnostic oligonucleotides responsible for the category-dependent clustering (the host-dependent clustering in this case). In order to study the oligonucleotides that may relate to host adaptation, we next identify diagnostic oligonucleotides for host-dependent separation on the tetranucleotide BLSOM. Six examples of diagnostic tetranucleotides for the host-dependent separation are presented in Figure 2C. A clear tendency is apparent; A- and U-rich oligonucleotides are more favored in humans than in avians (e.g., AUUA and AUUU); G- and C-rich oligonucleotides were more favored in avians than in humans (e.g., GAGG). This GC% effect was previously reported by Rabadan et al. [14]. However, GGCC and GGGG, which are composed only of G and/or C, are more favored in humans than in avians, and UCUU, a tetranucleotide rich in U, is preferred mainly in the avian territory. When we concern about interaction of viral RNAs (vRNAs and mRNAs) with various host factors (e.g., host proteins), oligonucleotide compositions, rather than the mononucleotide composition, will become important, because their interactions with host proteins primarily depend on oligonucleotide sequences in their sequences. This should also be true in considering escape processes from host antiviral mechanisms. To wrap up, oligonucleotide-BLSOM analyses of influenza viruses should provide valuable information of their host adaptation mechanisms (e.g., interactions of viral RNAs with host factors), which will become important for medical and pharmaceutical studies.

Chronological Changes Visualized for Human Viruses

In Figure 3, we next explain chronological changes of human seasonal strains using the same tetranucleotide BLSOM; only the lattice points containing human strains are shown as done in Figure 2B. In addition, the territory of human seasonal H1N1 (except for H1N1/09) and H3N2 strains in the following period is separately displayed in brown and blue; H1N1 and/or H3N2 strains isolated in 1930-1957, 1968-1974, 1975-1989, 1990-1999, 2000-2005, and 2006-2012 are displayed in brown and blue, respectively, in the respective panel. The seasonal strains isolated in 1930-1957 and 1968-1974 (i.e., the beginning of the epidemic of H1N1 and H3N2, respectively) are seen near avian and/or swine strains (red and blue in Figure 2A and blank in Figure 3), which have been estimated as their origin. Human seasonal strains are seen moving away from the avian and/or swine territory since 1930 (for H1N1) and 1968 (for H3N2), indicating the directional change of their oligonucleotide composition after

invasion into the human population. Therefore, at least from a specific point of view, genome sequence changes in the invader virus appear to be predictable, especially in an early stage of epidemics cycles. This has been found for H1N1/09 strains in our previous paper [7] even during the first one year, because of the high mutation rate and short generation time of influenza A viruses [12, 15].

To wrap up, BLSOM can visualize any categories of strains, in which experimental and medical groups will be interested, and therefore, has a power to visualize evolutionary histories of influenza viruses after invasion into new hosts.

Influenza B has caused repetitive epidemics only among humans and can be considered as it has already been well adapted to human cellular environments. In order to examine numerically whether the tetranucleotide composition of human seasonal A strains are approaching that of Influenza B with time, we have calculated Euclidean distance between the average composition in influenza B strains and that in H1N1 or H3N2 strains isolated in each year (Figure 4A). Euclidean distance shows the distance in the multidimensional scale (256 dimension for tetranucleotide composition); the distance between the strains that own an identical oligonucleotide composition is 0 and, as the difference in the oligonucleotide composition grows, the distance becomes larger.

Figure 3. Chronological changes for seasonal human subtype strains. Seasonal human H1N1 and H3N2 strains that are isolated in the different period are separately marked in brown and blue, respectively.

The distance between the influenza B strain and either H1N1 (red + marks) or H3N2 (blue x marks) A strain has become smaller over time (Figure 4A), showing that the tetranucleotide composition in A strains has become analogous to that in B strain during the repeating pandemics among humans and directional changes have been accumulating in genome sequences in the seasonal A strains.

H17N10 Strains Isolated from Bat

One of the most feared influenza viruses is the strain possessing antigen types, to which most humans do not possess antibodies, and therefore, the strains having caused epidemics in nonhuman sources (e.g., birds and pigs) attract attention.

Figure 4. Euclidean distance between seasonal human A and B strains. (A) Euclidean distance of tetranucleotide composition between influenza B strain and human seasonal strain (influenza A strain). Euclidean distance between the average composition in influenza B strains and that in H1N1 (+) or H3N2 (x) strains isolated in each year is plotted. (B) Euclidean distance of tetranucleotide composition between the bat and human seasonal strains. Euclidean distance between the average composition in bat strains and that in H1N1 (+) or H3N2 (x) strains isolated in each year is plotted.

Influenza A viruses are categorized by the combinations of antigen types: 16 and 9 types of HA and NA, respectively. As a natural host, birds are capable of transmitting all of the $16 \times 9 = 144$ types of influenza A strains. During recent years, new H17N10 strains, which greatly vary from known influenza A strain, have been isolated from the bats in Republic of Guatemala and estimated as being separated from birds far into the past [16]. As previously mentioned, BLSOM have a power to focus on and visualize a specific category of strains with no difficulty, even massive amounts of strains are analyzed. When paying attention to the three bat strains on BLSOM (arrowed in Figure 2A), these are located near influenza B strains and thus far away from the territory of birds which should be their original sources. This indicates that these bat H17N10 strains have been well adapted to mammalian cellular environments during repetitive epidemics in the mammalian host. So far judged from locations on BLSOM, cellular environments of human and bat appear to resemble each other, because human influenza B and bat A strains are located in a close vicinity.

Next, this prediction has been numerically checked, as done for the human influenza B strain in Figure 4A. In Figure 4B, we have plotted the Euclidean distance between the average composition in three bat H17N10 strains and that in H1N1 or H3N2 strains isolated in each year. As observed in Figure 4A, both H1N1 and H3N2 strains have shortened their Euclidean distances from the bat strains over time, indicating that cellular environments of human and bat appreciably resemble each other for the influenza virus growth. To sum up the findings in Figure 4A and B, the tetranucleotide composition most suitable to the growth in mammalian cells differs significantly from that for the growth in avian cells, and the avian strains invaded into a new host have to change their sequences for obtaining the composition suitable to the

new cellular environments. This directional change can offer information on predictions of viral sequence changes that will occur in the near future.

BLSOM for Codon Usage

Synonymous codon choice sensitively reflects constraints imposed on genome sequences and thus provides a sensitive probe for searching for molecular mechanisms responsible for the constraints, e.g., genome GC% and tRNA composition in the cases of micro-organisms [17-20]. We have previously found that BLSOM efficiently detects species-specific codon-choice patterns of micro-organisms, resulting in self-organization of genes according to microbial species [9]. Furthermore, in the case of genes horizontally transferred relatively recently, synonymous codon choice reflects primarily that of the donor, but not the recipient, genome. In the case of influenza viruses, we have previously found host-dependent clustering on codon-BLSOM [7], and in this chapter we introduce BLSOM for synonymous codon usage in influenza A and B virus genes (Figure 5A), by analyzing sequences including those published after our previous paper. In order to know codon biases for each strain, codon usages in eight genes are summed up for each strain.

Human and avian territories are again clearly separated from each other, and human H1N1/09 strains (dark green in Figure 5B) are again separated from the major human territory and surrounded by avian, equine and swine territories.

Synonymous codon-choice patterns of newly invading viruses, such as H1N1/09, should be close to those of the original host viruses, at least for a period immediately after the invasion. Codon choice will most likely shift towards the pattern of seasonal human viruses during many infection cycles among humans, because viruses depend on many cellular factors for their growth. Actually, the directional sequence changes in H1N1/09 towards the codon usage pattern of the seasonal human strains have been observed in our previous paper [7].

Figure 5. BLSOMs for codon usage. (A) Codon. BLSOM has been constructed for synonymous codon usage in 12,288 genes from influenza A and B strains, and lattice points are indicated in a color representing the host as described in Figure 2A. (B) Human subtype. On the Codon-BLSOM presented in (A), lattice points are indicated in a color representing the host as described in Figure 2B. (C) Occurrence levels of six codons, which are diagnostic for host-dependent separation, are indicated with different levels of two colors, as described in Figure 2C.

When we focus on diagnostic codons (Figure 5C), one simple tendency is observed. Codons ending with G or C are more favored for the avian strains than the human strains (AAG for Lys in Figure 5C), and vice versa. While the GC% effect is most apparent in two-codon boxes, this is also observed for many codons in four- or six-codon boxes (four examples in Figure 5C).

BLSOM for Amino-Acid and Peptide Composition

When we consider prediction of changes in virus sequences from a view of medical and pharmaceutical application, changes in amino acid sequences appear to be more informative than in nucleotide sequences, because amino acid sequences are more directly related to viral functions than genomic sequences; e.g., prediction of amino-acid sequence changes is very useful for designing vaccine and antiviral drug. Therefore, we next examine whether directional change of amino-acid and peptide composition can be detected with BLSOMs. We have constructed BLSOMs for mono amino-acid, dipeptide and tripeptide composition for a sum of major eight proteins (PB2, PB1, PA, HA, NP, NA, M1, and NS1) (Figures 6A and 7A, C).

Strains isolated from avian (red) and human (green) are again clustered (self-organized) according to host, forming their own large continuous territories. One simple tendency is immediately apparent. Human strains tend to prefer the amino acids coded by A- and/or U-rich codons (Asn, Ile, Lys, Phe, and Tyr; designated as A&U-AA), while avian strains appear to prefer the amino acids coded by C- and/or G-rich codons (Ala, Gly, Pro, and Arg; designated as C&G-AA) (Figure 6C). This shows that viral protein sequences are strongly affected by the host-dependent base compositions.

Figure 6. BLSOMs for amino-acid composition. (A) Amino acid. BLSOM has been constructed for amino-acid composition in 12,288 genes from influenza A and B strains, and lattice points are indicated in a color representing the host as described in Figure 2A. (B) Human subtype. On the Amino-BLSOM presented in (A), lattice points are indicated in a color representing the host as described in Figure 2B. (C) Occurrence levels of six amino acids, which are diagnostic for host-dependent separation, are indicated with different levels of two colors, as described in Figure 2C.

Figure 7. Oligopeptide-BLSOM for all influenza viruses. (A) Dipeptide-BLSOM. The color coding is the same as Figure 2A. (B) Occurrence levels of dipeptide, which are diagnostic for host-dependent separation, are indicated with different levels of two colors, as described in Figure 2C. (C) Tripeptide-BLSOM. The color coding is the same as Figure 2A. (D) Occurrence levels of tripeptide, which are diagnostic for host-dependent separation, are indicated with different levels of two colors, as described in Figure 2C.

Figure 8. Directional changes of amino-acid frequency in human seasonal strains for A&U-AA and C&G-AA. (A) The A&U-AA frequencies in human seasonal H1N1(+) and H3N2(×) strains are plotted according to the chronological order. (B) The C&G-AA frequencies in human seasonal H1N1(+) and H3N2(×) strains are plotted according to the chronological order.

In order to examine the directional changes of amino-acid composition during the human virus evolution, we calculate usage frequencies of A&U-AA and C&G-AA separately, and plotted the average of their frequencies in the seasonal human H1N1 or H3N2 strains isolated in each year using the red + or blue x mark (Figure 8). A&U-AAs for both H1N1 and H3N2 strains have been gradually growing since the beginning of their pandemic while C&G-AA appear to be reducing, showing the directional change at the amino-acid level, which is consistent with the direction observed for viral genome GC%.

When we consider functions of individual viral proteins, a combination of amino acids such as di- and tripeptide may become more important than the simple amino-acid composition; i.e., prediction of directional changes of peptide compositions may provide information more directly related to change in functions and/or antigenicities of viral proteins. On both di- and tripeptide BLSOMs, strains isolated from avian (red) and human (green) are again clustered (self-organized) according to host, forming their own large continuous territories (Figure 7A, 7C). Six examples of diagnostic di- or tri-peptide for the host-dependent separation are presented in Figure 7B and 7D; most human strains prefer KL composed only of A&U-AAs and most avian strains prefer AR composed only of C&G-AAs. This is consistent to the prediction from their genome GC%. However, the trend of not relying on viral genome GC% is also seen for various di- and tri-peptides (e.g., RAA in Figure 7B). Host-dependent composition of the latter type of peptides appears to be interesting from a view of their biological significance, and therefore, detailed analyses of these peptides are in progress by our group.

CONCLUSION

Influenza viruses isolated from humans and birds differed in mono- and oligonucleotide composition and in mono amino-acid and peptide composition. Time-dependent directional changes of these compositions, which are observed for the newly invaded viruses into the human population from other animal hosts, can provide predictive information about sequence changes of the invaded viruses, which should be useful for medical and pharmaceutical purposes. Basing on the findings obtained by BLSOM analyses, we have previously proposed a strategy for efficient surveillance of potentially hazardous nonhuman strains that may cause new pandemics with a high probability [7]. Millions of influenza and other virus sequences will become available in the near future because of their medical and social importance, and BLSOM can characterize such big data without difficulty and support efficient knowledge discovery.

ABSTRACT

An oncogene is a modified gene, or a series of nucleotides that encode a protein, and direct the cell to the development of a neoplastic phenotype. Usually, oncogenes are involved in tumor development and increase the possibility that the development (proliferation and differentiation) of a cell directs towards cancer. New researches indicate that small ribonucleic acids (RNA) of 21-25 nucleotides, called micro RNA (miRNA), can control these genes through down-regulation. The first oncogene was discovered in 1970 and named Src. Src was first discovered in a retrovirus of chickens. In 1976, J. Michael Bishop and Harold E. Varmus of the University of California showed that this oncogene was a defective proto-oncogene present in many organisms including humans. For their studies Bishop and Varmus were awarded of the Nobel Prize in 1989. A proto-oncogene is a normal gene that can become oncogenic due to mutations or to increased expression. Proto-oncogenes encode proteins that regulate the cell cycle and differentiation. They may also be involved in the signal transduction of the start of mitosis. A proto-oncogene becomes an oncogene even with minimum modifications of its original functions. There are two basic types of activation: 1) a mutation of nucleotides which produce a different protein causing: a) increased enzymatic activity of the protein; b) the loss of regulatory sites; and c) the creation of hybrid proteins; and 2) an increase of the concentration of proteins caused by: a) an increase of gene expression (through misregulation); b) an increase of stability (half-life) of the protein; and c) a duplication or amplification of the gene coding for the protein. Growth factors (GF), or fitogens, are usually secreted in a few

* Corresponding Author's Email: cicomp@tin.it.

cells specialized to induce proliferation in a paracrine, autocrine, or endocrine manner. If a cell that normally does not produce GF suddenly begins to produce them (because it has developed an oncogene), this induces the proliferation, without control, to adjacent cells (paracrine action) and to its cell type (autocrine action) increasing secretion. There are six known classes of protein kinases (PK) and related proteins that are potential oncogenes: 1) tyrosine kinase receptor (TKR), which becomes constitutively (permanently) activated, such as the epidermal growth factor receptor (EGFR), the platelet-derived growth factor receptor (PDGFR), and the vascular endothelial growth factor receptor (VEGFR); 2) cytoplasmic TK, such as TK enzymes of the Src family, Syk-ZAP-70 and Bruton's TK (BTK); 3) regulatory guanosine triphosphate (GTP)ase, like Ras; mutations that activate permanently Ras are found in 20-25% of all human tumors and up to 90% in some types of cancer, such as pancreatic ones; 4) cytoplasmic serine/threonine kinase and its regulatory units, such as Raf kinase and cyclin-dependent kinase (CDK); 5) adapter proteins in signal transduction (for example in the apoptotic pathway); and 6) transcription factors, for example the Myc gene. A large number of genes have been identified as proto-oncogenes. Most of them are responsible for the production of a positive signal that induces cell division. Other proto-oncogenes play an important role in the regulation of cell death. As mentioned before, the "altered" versions of these genes (oncogenes) may induce the cell to replicate unruly. Such a development can take place even in the absence of normal pro-growth signals, as for example the one provided by GF. A key feature in the activity of oncogenes is that a single altered copy is sufficient to induce an unregulated growth. Such behavior is in contrast with the one typical of tumor-suppressor genes (TSG) for which it is necessary that both copies of the gene are defective for triggering a process of abnormal cell division. Proto-oncogenes that have been identified until now have very different functions within the cell. Despite the differences in their normal functions, these genes all have the characteristic to contribute to unregulated cell division when present as mutated (oncogenic). The mutated proteins sometimes retain some features of their own, but are no longer sensitive to the regulation systems that determine and control the normal form of the protein itself. In this chapter we overview the role of oncogenes in gynecological pathology.

INTRODUCTION

During the past decades, the expansion of molecular biology has had a pivotal role in understanding the basis of cancer development and progression. In addition, real advances have been made in the application of deoxy-ribonucleic acid (DNA) recombinant technology to cancer therapy and patient management [1]. Early studies designed to investigate the molecular basis of oncogenesis indicated the existence of discrete genes which could cause neoplastic transformation of normal cells in vitro. These genes (which became known as oncogenes) were originally thought to be derived from oncogenic retroviruses and neoplastic transformation was believed to be the result of infection of normal cells by an oncogenic retrovirus. However, recent studies have demonstrated that normal eukaryotic cells contain gene sequences which are highly homologous to oncogenes but which do not cause neoplastic transformation. These genes (termed proto-oncogenes) have been found to code for proteins which are intimately involved in the regulation of mitosis. These include growth factors, receptors for growth factors, proteins (such as protein kinases [PK] and guanosine triphosphate [GTP] binding proteins [BP]) which transduce exogenous signals through the plasma membrane, and nuclear BP. Thus, if the function or control of a proto-oncogene (or its product) is altered by mutation,

gene rearrangement, or translocation, its effects on the cell will also change. This, in turn, can lead to the loss of normal mitotic control. The tumorigenic process is, of course, much more complicated than just unchecked cell growth. However, the insights into the molecular basis of cellular regulation have suggested new approaches to the early diagnosis of cancer and may ultimately lead to the development of more effective treatment protocols [2].

Gynecologic malignancies, representing 13% of all cancers affecting women, have a major impact on women's health. Cervical, endometrial, and ovarian cancers comprise the majority of these tumors and contribute significant morbidity and mortality to the female population. While cervical and endometrial cancers can be detected early in their development, sadly, many patients present with advanced disease, as do the majority of patients with ovarian cancer. Unfortunately, advanced cases of these malignancies are usually lethal despite modern therapeutic modalities. In order to impact upon these grim statistics, gynecologic researchers have turned to molecular biology in an attempt to elucidate the etiology of these cancers. Recent research describing dominant oncogene and tumor-suppressor gene (TSG) mutations common to these malignancies is providing a basis for the molecular genesis of these cancers. This information should offer new avenues for the development of early detection and chemoprevention, as well as novel treatment strategies [3].

ONCOGENES IN GYNECOLOGICAL CANCERS

The multifactorial process of carcinogenesis involves mutations in oncogenes, or TSG, as well as the influence of environmental etiological factors. Common DNA polymorphisms in low penetrance genes have emerged as genetic factors that seem to modulate an individual's susceptibility to malignancy. Genetic studies, which lead to a true association, are expected to increase understanding of the pathogenesis of each malignancy and to be a powerful tool for prevention and prognosis in the future [4]. Cancer is a genetic disease, and inherited or acquired genetic defects contribute to the initiation and progression of cancer [5]. The genes responsible for hereditary cancers such as retinoblastoma, colorectal cancer, and breast cancer have been identified through application of positional cloning from human molecular genetics. Linkage analysis is a powerful method to locate a disease gene, however a precise genetic model, detailing the mode of inheritance, gene frequencies and penetrance, is required for parametric methods, but not for nonparametric methods. The nonparametric methods ignore unaffected people, and look for alleles that are shared by affected individuals within nuclear families as well as extended families. Hence, the methods usually have been performed to identify disease genes in many hereditary diseases [6].

Comparative genomic hybridization (CGH) is a powerful new molecular cytogenetic method which allows genome-wide mapping of regions with DNA sequence copy number changes (both increases and decreases) in a single experiment without previous knowledge of the locations of the regions of abnormality. CGH is based on *in situ* hybridization (ISH) of differentially labeled total genomic tumor DNA and normal DNA to normal human metaphase chromosomes. After hybridization, copy number variations among the sequences in the tumor DNA are detected by measuring the tumor/normal fluorescence intensity ratio for each locus in the target chromosomes. Many previously unknown chromosomal regions with relative copy number changes have been detected in various tumors by CGH. Some changes have been

identified as genetic markers associated with biological and clinico-pathological characteristics (i.e., histopathological grade and clinical outcome) [7, 8].

Advances in molecular biology have facilitated the recent investigation of gynecological malignancies. The presence of certain oncogenes within gynecological tumors indicates that transformation may be associated with genetic alteration of normal regulatory processes. Several oncogenes have been implicated in the transformation of gynecological tissues [9]. Among them, the human epidermal growth factor receptor (EGFR) 2 (HER-2)/neu and micro-ribonucleic acids (miRNA) are two examples of the most often studied.

The HER-2/neu proto-oncogene (also known as c-erbB2, neu, and HER2) encodes a 185-kDa trans-membrane glycoprotein with intrinsic tyrosine kinase (TK) activity that resembles the receptor for EGF. Aberrant HER-2/neu protein overexpression occurs in human gynecologic adenocarcinomas, including those of the ovary, endometrium, breast, fallopian tube, and cervix, and is secondary to gene amplification and/or overexpression of the p185HER2 protein. Overexpression of HER-2/neu was found to be a poor prognostic factor for survival from advanced-stage ovarian cancer, node-positive breast cancer, and endometrial cancer. Although a specific ligand has not been definitively identified, HER-2/neu may have unusually complex activation pathways because it can form both homodimeric and heterodimeric associations with other related receptor proteins. Preliminary findings suggest that serum HER-2/neu levels may be used as a tumor marker in a subset of patients with tumors that overexpress the HER-2/neu receptor. Receptor-targeted therapeutics currently being studied include the use of receptor antibodies, liposomally delivered antisense DNA, antigen-activated cytotoxic lymphocytes (CTL), and adenovirus-mediated E1A delivery to overexpressing tumor cells. HER-2/neu appears to play an important role in the biologic behavior of ovarian, endometrial, and breast cancers and holds potential as a target for oncogene-directed therapies [10].

miRNA are 21-22 nucleotide non-coding RNA that regulate gene expression and play fundamental roles in biological processes. These small molecules bind to target messenger-RNA (mRNA), leading to translational repression and/or mRNA degradation. Aberrant miRNA expression is associated with several human diseases such as cancer, cardiovascular disorders (CVD), inflammatory diseases, and gynecological pathology. miRNA have a role in four gynecological disorders that affect the ovary or the uterus, one benign and frequent disease (endometriosis) that is classified as a tumor-like lesion and three malignant gynecological diseases (endometrial, cervical, and ovarian cancers). In cancer, miRNA have an important role as regulatory molecules, acting as oncogenes (oncomiR) or tumor-suppressors. Endometrial cancer is one of the most frequent gynecological malignancies in the developed countries. Cervical cancer, also one of the most common cancers in women, is associated with high risk Human Papillomaviruses (HPV), although this infection alone may not be enough to induce the malignant transformation. Ovarian cancer is the fifth leading cause of all cancer-related deaths among women. Over 80% of cases are diagnosed at an advanced stage, with a reduced five-year survival rate. Recent studies have shown that miRNA are aberrantly expressed in different human cancer types, including endometrial, cervical, and ovarian cancer, and that specific dysregulated miRNA may act as biomarkers of patients' outcome. Recently, miRNA have been detected in serum and plasma, and circulating miRNA expression profiles have now been associated with a range of different tumor types. Their accessibility in peripheral blood and stability, given the fact that miRNA circulate confined within exosomes, make researchers foster hope in their role as emerging biomarkers of cancer and other disorders. The development

of therapies that might block the expression or mimic the functions of miRNA could represent new therapeutic strategies for any of the aforementioned gynecological disorders [11, 12].

Breast Cancer

Breast cancer is the most common female malignancy in many industrialized countries [13]. Colony stimulating factor (CSF-1) and its receptor (CSF-1R, product of *c-fms* proto-oncogene) were initially implicated as essential for normal monocyte development as well as for trophoblastic implantation. However, studies have demonstrated that CSF-1 and CSF-1R have additional roles in mammary gland development during pregnancy and lactation. This apparent role for CSF-1/CSF-1R in normal mammary gland development is very intriguing because this receptor/ligand pair has also been found to be important in the biology of breast cancer, in which abnormal expression of CSF-1 and its receptor correlates with tumor cell invasiveness and adverse clinical prognosis. Recent findings also implicate tumor-produced CSF-1 in promotion of bone metastasis in breast cancer, and a certain membrane-associated form of CSF-1 appears to induce immunity against tumors. Recent findings on the role of CSF-1 and its receptor in normal and neoplastic mammary development may elucidate potential relationships of GF-induced biological changes in the breast during pregnancy and tumor progression [14].

The mammary gland seems to be the only organ that is not fully developed at birth. Estrogens stimulate breast tissue via estrogen receptors (ER). In the mammary gland, ER-mediated mechanisms have been shown to regulate:

1. various GF, such as transforming GF (TGF)-alpha and TGF-beta;
2. enzymes, such as cathepsin D and plasminogen-activator;
3. proto-oncogenes, such as *c-fos*, *c-myc*, and *HER-2/neu*;
4. cyclines and other regulatory substances that provide signaling systems for cell division and differentiation; and
5. other steroid receptors and EGFR.

Estrogen target genes contain estrogen-responsive elements. In these genes, transcription will be activated through interaction with the estrogen/ER protein complex. Subsequent activation of proto-oncogenes provides an explanation for the stimulating effect of estrogens on the glandular breast. Progesterone may be the key in influencing the risk of breast cancer with the peak of mitotic activity in the breast during the luteal phase of the menstrual cycle. On the other hand, in human breast cancer cell lines, both proliferation and inhibition have been observed with various progestational agents.

Relevant biological and clinical issues are pregnancy and exposure to exogenous hormones. The intense hormonal stimulation of pregnancy (both estrogen and progesterone) has no adverse impact on the course of breast cancer. Pregnancy, with its mammatogenic differentiation, results in the protection of this organ from carcinogenesis. Characterization of specific lobular morphology serves as an indicator of the level of differentiation achieved by the organ, and thus provides means to assess the risk of the gland undergoing neoplastic transformation when exposed to given agents. Sufficient evidence exists to indicate the possibility of a slightly increased risk of breast cancer after approximately one decade of

postmenopausal estrogen use. A review of the epidemiologic studies of postmenopausal hormone replacement therapy (HRT) and the risk of breast cancer fails to provide definitive evidence. Recent information derives from observations of cellular proliferation, plasma and tissue estradiol and progesterone receptor levels, and the percentage of apoptotic epithelial cells in human breast tissue. Several studies suggest that short-term, continuous combined HRT does not increase breast cancer recurrence or mortality. The participation of sexual hormones in the mammatogenic process during pregnancy might serve as an intermediate end point in assessing the effectiveness of hormones as chemopreventive agents. Investigations based on history, and breast morphology, should enable us to select estrogens and progestogens for HRT, and adopt optimal therapeutic regimens [15].

Breast cancer emerges by a multistep process which can be broadly equated to transformation of normal cells via the steps of hyperplasia, premalignant change, and carcinoma in situ (CIS). The elucidation of molecular interdependencies, which lead to development of primary breast cancer, its progression, and its formation of metastases is the main focus for new strategies targeted at prevention and treatment. Cytogenetic and molecular genetic analysis of breast cancer samples demonstrates that tumor development involves the accumulation of various genetic alterations including amplification of oncogenes and mutation or loss of TSG. Amplification of certain oncogenes with concomitant overexpression of the oncoprotein seems to be specific for certain histological types. Loss of normal tumor-suppressor protein function can occur through sequential gene mutation events (somatic alteration) or through a single mutational event of a remaining normal copy, when a germ-line mutation is present. The second event is usually chromosome loss, mitotic recombination, or partial chromosome deletion. Chromosome loci 16q and 17p harbor TSG, which seem to be pathognomonic for the development or progression of a specific histological subtype. There are an overwhelming number of abnormalities that have been identified at the molecular level which fit the model of multistep carcinogenesis of breast cancer. When the functions of all of these genes are known and how they participate in malignant progression, we will have the tools for a more rational approach to diagnosis, prevention, and treatment. A key critical long-term step in the molecular analysis of breast cancer will be to link the specific molecular damage with the effects of environmental carcinogens [16].

The question addressed is how far a multi-step progression model for sporadic breast cancer would differ from that for hereditary breast cancer. Hereditary breast cancer is characterized by an inherited susceptibility to breast cancer on basis of an identified germ-line mutation in one allele of a high penetrance susceptibility gene (such as breast cancer [BRCA]1, BRCA2, checkpoint kinase [CHEK]2, tumor protein [TP]53, or phosphatase and tensin homolog [PTEN]). Inactivation of the second allele of these TSG would be an early event in this oncogenic pathway (Knudson's "two-hit" model). Sporadic breast cancers result from a serial stepwise accumulation of acquired and uncorrected mutations in somatic genes, without any germ-line mutation playing a role. Mutational activation of oncogenes, often coupled with non-mutational inactivation of TSG, is probably an early event in sporadic tumors, followed by more, independent mutations in at least four or five other genes, the chronological order of which is likely less important. Oncogenes that have been reported to play an early role in sporadic breast cancer are MYC, cyclin D1 (CCND1), and erbB2 (HER2/neu). In sporadic breast cancer, mutational inactivation of BRCA1/2 is rare, as inactivation requires both gene copies to be mutated or totally deleted. However, non-mutational functional suppression could result from various mechanisms, such as hypermethylation of the BRCA1 promoter or binding

of BRCA2 by EMSY. In sporadic breast tumorigenesis, at least three different pathway-specific mechanisms of tumor progression are recognizable, with breast carcinogenesis being different in ductal versus lobular carcinoma, and in well differentiated versus poorly differentiated ductal cancers. Thus, different breast cancer pathways emerge early in the process of carcinogenesis, ultimately leading to clinically different tumor types. As mutations acquired early during tumorigenesis will be present in all later stages, large-scale gene expression profiling using DNA microarray analysis techniques can help to classify breast cancers into clinically relevant subtypes [17].

C-erbB-2 (neu) oncogene was found on the cell membrane in primary breast cancers. No obvious relation was found between neu oncogene, age, and lymph node status and tumor size. There was a tendency towards smaller primary tumors and more ER-negative tumors in the oncogene-positive group. No case of distant metastasis during follow-up was found among the oncogene-negative patients, while several oncogene-positive patients developed such metastases. This suggests that the neu oncogene is an independent prognostic factor, which might predict the development of distant metastasis. Further studies including more patients and long-term survival analysis are, however, needed in order to evaluate the prognostic significance of the neu oncogene [18]. Pooling of microarray datasets seems to be a reasonable approach to increase sample size when a heterogeneous disease like breast cancer is concerned. Different methods for the adaption of datasets have been used in the literature. Influences of these strategies using a pool of Affymetrix U133A microarrays from breast cancer samples have been analyzed. Data on the resulting concordance with biochemical assays of well-known parameters highlight critical pitfalls. The cutoffs derived by a method for the inference of cutoff values directly from the data without prior knowledge of the true result displayed high specificity and sensitivity. Markers with a bimodal distribution like ER, progesterone-receptor (PgR), and HER2 discriminate different biological subtypes of disease with distinct clinical courses. In contrast, markers displaying a continuous distribution like proliferation markers as Ki67 rather describe the composition of the mixture of cells in the tumor [19].

The development of new chemotherapeutic agents and concepts of radiation therapy, administered as primary, adjuvant, and palliative therapy, has led to new perspectives in breast cancer therapy. Apart from conventional chemotherapy, recently developed novel agents interfere with molecular mechanisms that are altered in cancer cells. Those targets are not necessarily breast cancer-specific. Promising strategies include inhibition of GF receptors, blocking of tumor angiogenesis and signal transduction pathways, modulation of apoptosis, cancer vaccination, and inhibition of invasion and metastasis [20]. Approximately one fourth of all women diagnosed with early breast cancer present with tumors that are characterized by erbB2 amplification. While the associated HER-2/neu receptor over-expression results in a high risk of relapse and poor prognosis, these tumors also represent a target for a selective monoclonal antibody therapy with trastuzumab (Herceptin). The combination of trastuzumab with chemotherapy has led to a considerable reduction of recurrences and to a significant reduction in breast cancer mortality both in the adjuvant and metastatic setting. Unfortunately, despite HER-2/neu over-expression, not all patients equally benefit from trastuzumab treatment, and almost all women with metastatic breast cancer eventually progress during antibody therapy. Moreover, trastuzumab is burdened with cardiotoxicity, thus increasing the risk of symptomatic congestive heart failure. In addition, the marginal costs for one year therapy of trastuzumab-based therapy, which is currently considered to be the most effective treatment regimen in the adjuvant setting, may amount for up to US\$ 40.000. Testing for erbB2

oncogene amplification by fluorescence ISH (FISH) and chromogenic ISH (CISH), respectively, and staining for HER-2/neu receptor over-expression by immunohistochemistry (IHC) represent the current standard for determining patient eligibility for trastuzumab-based therapy. However, while the negative predictive value of these assays for predicting the absence of benefit from trastuzumab-based therapy is sufficiently high, their positive predictive value remains insufficient, i.e., only a proportion of patients selected by these tests substantially benefit from trastuzumab-containing regimen. Accordingly, over the last years a number of biomarkers have been evaluated in their potential to predict response to trastuzumab-based therapies. These include markers of activation of HER-2/neu (e.g. tyrosine phosphorylated HER-2/neu in tissue and cleaved HER-2/neu extracellular domain in serum) and its dimerization partners (e.g., EGFR), respectively, but also components of HER-2/neu-induced downstream signaling pathways that are crucial for the growth inhibitory effects of trastuzumab (e.g., PTEN and phosphatidylinositol 3-kinase [PI3K]). Other parameters, such as topoisomerase-II alpha and c-myc co-amplifications, have also been identified as potentially useful predictors of response to trastuzumab-based chemotherapy regimen. While the benefit of these predictive biomarkers in the metastatic setting is currently explored, their usefulness in the adjuvant setting is still largely unknown. It is, however, undisputable that, within the group of HER-2/neu over-expressing tumors, further response predictors are needed in order to minimize trastuzumab-associated side effects, and to reduce the considerable societal costs that are associated with trastuzumab-based treatment regimen [13].

As a consequence of the success with the HER2 targeting antibody trastuzumab (Herceptin) in the treatment of early stage and metastatic breast cancer, several antibodies inhibiting cellular signaling of vascular EGF (VEGF) and EGFR were tested with respect to their efficacy in breast cancer. In phase II and III clinical trials the humanized anti-VEGF antibody bevacizumab (Avastin), alone or in combination with capecitabine, exhibited responses in patients with metastatic breast cancer. Recent developments focus on small molecules interfering with different signal transduction pathways in tumor cells. Numerous inhibitors of EGF and VEGF TK receptor (TKR) and farnesyl transferases are in early stages of clinical development for breast cancer. Another promising approach is the targeting of endothelins and their two G-protein coupled receptors (ET(A)R and ET(B)R). Due to the heterogeneity of disease and varying response to conventional systemic therapies, these new perceptions may lead to substantial patient benefit and provide a promising basis for future clinical application [21]. Other further developed compounds show promising results in clinical studies as a second generation of GF inhibitors. Different approaches in anti-angiogenic therapy are under preclinical and clinical phase-II trials. Pro-apoptotic agents show synergistic effects with docetaxel in a clinical phase-I trial. Other compounds that target heat shock protein 90 (HSP 90), histone deacetylase, and 3-hydroxy-3-methyl coenzyme A (HMG-CoA) reductase target atypical apoptotic pathways being lethal to tumor cells only but not to normal tissue, suggesting a tumor-specific way of action. Matrix metalloproteinases (MMP) inhibitors have been demonstrating promising results in patients with refractory malignant pleural effusion in a phase-I trial. Several TK inhibitors (TKI) currently under clinical investigation preliminarily show hopeful results in patients with advanced breast cancer. Furthermore, recent progress in defining the immunogenic epitopes of tumor antigens has rejuvenated the interest in cancer vaccines. Typical dose escalation studies leading to the highest clinically still tolerated dose do not appear to be equally appropriate for the estimation of efficiency of those compounds as for conventional cytotoxic regimes. Rather, escalation up to an amount of therapeutic agent that is

sufficient for maximum target inhibition should be promoted, where classical measures of cytoreduction such as complete or partial remission are replaced both by time to progression and treatment failure as an appropriate measure of the efficacy of an agent [20]. Clinical trial data indicate that epirubicin-based adjuvant treatment of breast cancer is associated with marked improvement in relapse-free and overall survival compared with traditional cyclophosphamide (CTX)/methotrexate (MTX)/5-fluorouracil (5-FU). The outcomes are comparable to those achieved with sequential use of doxorubicin/CTX and paclitaxel. Dose intensification of epirubicin is feasible, with tolerable side effects and no increased risk of cardiotoxicity beyond that expected. Clinical trial data coupled with pharmacokinetic evidence provide a strong foundation and rationale for current and future investigation of epirubicin in combination with the taxanes in the adjuvant setting. An ongoing German study is evaluating epirubicin/CTX in combination with trastuzumab as first-line therapy of metastatic breast cancer in patients whose tumors overexpress HER2/neu protein. These results, particularly the tolerability of this regimen, will form the basis for future adjuvant and neoadjuvant studies of epirubicin/trastuzumab-based regimens [22].

Ovarian Cancer

Epithelial ovarian cancer is the leading cause of death from gynecological cancers, largely owing to the development of recurrent intractable disease. Surgical and chemotherapeutic advances have been made, yet the cause of ovarian oncogenesis is poorly understood. Only a small number of distinct genetic mutations are known to contribute to ovarian carcinogenesis. Furthermore, understanding mechanistic genotype-phenotype links is complicated by frequent aneuploidy. Recognition of the familial clustering has focused investigators in the direction of isolating genetic susceptibility loci for ovarian cancer. The familial clustering of breast and ovarian cancers, as well as the chromosomal alterations and oncogenes identified, have all contributed to our understanding of the genetic factors involved in the development of ovarian cancer. Epigenetic deregulation is even more prominent, and ovarian cancers are replete with such aberrations that repress tumor-suppressors and activate proto-oncogenes. Research on cytogenetic abnormalities have led to the identification of oncogenes and TSG, which have contributed to a multistep model of molecular oncogenesis. Epigenetic therapies are emerging as promising agents for resensitizing platinum-resistant ovarian cancers. These drugs may also have the potential to alter epigenetic programming in cancer progenitor cells and provide a strategy for improving therapy of ovarian cancer [23, 24].

As with many other tumors, the origin and development of ovarian cancer is constituted by several molecular mechanisms, many of which are still unknown. Our understanding of ovarian cancerogenesis has been hampered by the lack of a well-defined precursor lesion, the lack of knowledge about tumor progression, and by the relative inaccessibility of the ovaries in the abdominal cavity. Furthermore, data in the literature are incomplete and often contradictory, and they are mainly founded on results obtained on cell lines and not on observations based on the *in vivo* study of ovarian cancer. Despite this situation, the study of control mechanisms of proliferation and differentiation in normal ovarian functioning has enabled clinicians to identify certain growth factors and oncogenes which seem to have an important role in the neoplastic transformation of ovarian tissue. Recent studies using experimental models allow us to better

define the fundamental mechanisms of carcinogenesis from the serous ovarian cells and of invasion of the abdominopelvic cavity by proximity [25, 26].

Most ovary carcinomas are epithelial tumors. Approximately 80-90% of adult ovarian cancers are assumed to originate from ovarian surface cells. The morphology of the ovarian surface epithelium changes constantly, exhibiting features such as crypts, inclusion cysts, villous processes, and different forms of Müllerian epithelium. The unique nature of ovarian surface features and their absence in the immediately adjacent peritoneal mesothelium suggest that local factors may play an important part in modifying the growth and morphology of the ovarian surface epithelium. Recent studies tend to emphasize oncogene activation, along with concomitant cytogenetic changes, in the development of ovarian cancer [27]. It has been proposed that epithelial ovarian cancers are of unifocal origin and arise from a single cell. Many alterations occur during the multistep carcinogenesis including interaction of peptide growth factors, activation of proto-oncogenes, and loss of TSG. Increased activity of TGF- α and decreased activity of TGF- β may contribute to the development of many ovarian cancers. Loss of TGF- β responsiveness has been associated with the down-regulation of c-myc expression in the development of ovarian cancer. Alternative expression of many oncogenes including ras, erbB2, and c-myc, were detected in many studies. Protein 53 (p53) mutation was detected in 50% of advanced ovarian cancer, suggesting that loss of TSG function facilitates transformation. Serum parameters like alpha-fetoprotein (AFP), carcinoembryonic antigen (CEA), cancer antigen 125 (CA-125), immunosuppressive acidic protein (IAP), lactate dehydrogenase (LDH), sialic acid (SA), TGF- α , and macrophage-CSF (M-CSF) have been used as ovarian tumor markers. None of these biochemical markers is presently consistent and specific enough to be an early detection for ovarian cancers [28].

However, the development and progression of epithelial ovarian cancer can be correlated with various biologic and molecular factors. Tumor growth has been associated with aberrant and dysfunctional expression and mutation of various genes. These genetic defects include oncogene over-expression, amplification or mutation, aberrant TSG expression or mutation, and the inappropriate expression of cytokines and GF and/or the cellular receptors for these molecules. Dysregulation of host immune responses may also play a permissive role in the pathogenesis of the disease. Since ovarian cancer has been associated with the frequency of ovulation, the repeated proliferation of epithelial cells may increase the chance of a genetic accident that could contribute to the activation of an oncogene or inactivation of a suppressor gene. These events, combined with the inherent ability of ovarian epithelial cells to respond to and produce various cytokines and GF, could promote oncogenesis [29]. Recent evidence indicates that inherited and acquired genetic mutations are the driving force behind carcinogenesis and cellular transformation. A number of proto-oncogenes and TSG are associated with ovarian carcinomas, including p53, BRCA1, and BRCA2, mismatch repair genes such as human mutS homolog 2 (hMSH2) and human mutL homolog 1 (hMLH1), and PTEN, HER-2/neu, K-ras, fms, and active serine/threonine PK 2 (AKT2). Novel genes recently implicated in ovarian tumorigenesis include novel ovarian epithelial Y2 (NOEY2), ovarian cancer-associated gene 1 protein (OVCA1), and PI3K. Although no singular gene alteration has been shown to initiate transformation in the ovarian epithelium, elucidation of the complex molecular and cellular mechanisms involving these known gene mutations may result in new clinical management strategies [30]. Ovarian cancer is caused by genetic alterations that disrupt proliferation, apoptosis, senescence, and DNA repair. Approximately 10% of ovarian cancers arise in women who have inherited mutations in cancer susceptibility genes (BRCA1 or

BRCA2). The ability to perform genetic testing allows identification of women at increased risk who can be offered prophylactic oophorectomy or other interventions aimed at preventing ovarian cancer. The vast majority of ovarian cancers are sporadic, resulting from the accumulation of genetic damage over a lifetime in the absence of a familial or heritable component. Several specific genes involved in ovarian carcinogenesis have been identified, including the p53 TSG and HER2/neu and PIK3CA oncogenes. The recent availability of expression microarrays has facilitated the simultaneous examination of thousands of genes, and this promises to extend further our understanding of the molecular events involved in the development of ovarian cancers. Hopefully, this knowledge can be translated into effective screening, treatment, surveillance, and prevention strategies in the future [31, 32]. The inability to identify relevant markers for pre-symptomatic screening in early stage or “pre-invasive” ovarian cancer has plagued investigators and clinicians facing the problems of early detection. The characteristic late stage of disease at initial presentation has hindered our understanding of the biologic progression and stepwise molecular alterations that result in ovarian carcinoma. To date, most screening studies have focused on identifying early anatomic changes using ultrasound or fluctuations in serum biomarkers such as CA-125. These screening methodologies have proven inadequate in both sensitivity and specificity for early stage ovarian cancer detection. Molecular analysis of ovarian carcinomas has revealed alterations in oncogenes and TSG associated with these tumors. The HER-2/neu oncogene, a member of the EGF family, is amplified or over-expressed in approximately 25-30% of ovarian carcinomas. Significant data substantiate an important role for HER-2/neu in the pathophysiology of ovarian cancer. While potentially an attractive surrogate endpoint biomarker (SEB), serum HER-2/neu levels have not proven to be a useful screening modality. In response to the urgent need for improved early detection for ovarian cancer, current research efforts include:

- 1) differential hybridization studies between normal and malignant ovarian epithelium to define potentially unique ovarian cancer antigens which may ultimately have utility;
- 2) defining physical alterations that occur in malignant ovarian tissues using implanted telemetry systems;
- 3) studies using positron emission tomography (PET) to detect changes in glucose metabolism between normal and malignant ovarian tissues; and
- 4) screening studies using a 3-dimensional (3-D) ultrasound unit to improve the accuracy of this technique in recognizing early neoplastic changes.

By taking diverse approaches to tackle this problem, an improved understanding of ovarian carcinogenesis should translate into the identification of appropriate SEB for early detection [33].

The discovery of peptide GF and cancer-causing genes (oncogenes and TSG) has provided us with the exciting opportunity to begin to understand the molecular pathology of human ovarian cancer. Activation of several genes, including HER-2/neu, myc, ras, and p53 have been described in some ovarian cancers. In addition, some proto-oncogenes such as the EGFR (erbB) and the M-CSF receptor (fms) are expressed along with the respective ligands (peptide GF) in some ovarian cancers. Although the studies reviewed represent a promising beginning, we remain far from a comprehensive understanding of growth regulation and transformation of human ovarian epithelium [34]. Molecular genetic evaluation of ovarian cancer primarily has utilized mutation analysis, IHC techniques, and loss of heterozygosity (LOH) studies. Over-

expression of the HER-2/neu oncogene is present in approximately one third of ovarian cancers and is associated with poor prognosis. Mutations of the K-ras oncogene have been identified in a similar proportion of mucinous ovarian tumors, including borderline tumors. Some authors have frequently detected LOH on chromosome 17, including the p53 and BRCA1 loci, and at 17p3.3 and 1717q22-23. Genetic linkage analysis indicates that the majority of inherited ovarian cancers are caused by mutations in the BRCA1 gene. Mutations in mismatch repair genes have been identified in ovarian cancers that occur as part of the hereditary non-polyposis colon-rectal cancer (HNPCC) syndrome. Sporadic ovarian tumors are the end result of a complex pathway involving multiple oncogenes and TSG, including HER-2/neu, K-ras, p53, BRCA1, and additional TSG on chromosome 17. The majority of inherited ovarian cancers are due to mutations in the BRCA1 gene, which appears to be a TSG [35]. K-ras activation is specific for mucinous tumors including adenomas, borderline tumors, and carcinomas, suggesting that K-ras activation may be associated with the mucinous differentiation rather than malignant transformation. Inactivation of p53 is detected in 30-40% of ovarian carcinoma. Mutations are more frequently observed in serous carcinomas, but not found in adenomas or rarely found in borderline tumors, suggesting that p53 mutations may be directly involved in malignant transformation. TGFbeta-2 mutations are found in 50% of endometrioid adenocarcinoma (EAC), but rarely in other type. Loss of deleted in colorectal carcinoma (DCC) mRNA expression is found in 50% of serous carcinomas but less frequently in other type. Loss of DCC expression is rare in borderline tumors and adenomas, suggesting that inactivation of DCC may be directly involved in malignant transformation. Microsatellite instability (MI) is found in 17% of ovarian carcinomas, and is frequently found in EAC. Although inactivation of p16 by point mutation or deletion is rare, p16 inactivation by loss of expression is relatively common [36].

The classic prognostic parameters are insufficient for predicting the prognosis of the individual patient. Knowledge of molecular and biological factors which are responsible for the development and progression of ovarian cancer may improve the prediction of prognosis. Recent data both on factors associated with the development and control of ovarian cancer cells and on DNA ploidy suggest that steroid and peptide hormones have a role in disease etiology and progression, and that peptide GF and cytokines, oncogenes and TSG, by their impact on mitosis and cell number may influence the rate of mutations, which could confer malignant transformation. DNA ploidy is an objective independent prognostic factor. DNA aneuploidy indicates high risk, diploidy low risk. Only tumors shown to be DNA diploid by flow-cytometry and image cytometry are considered diploid. S-phase fraction is currently not reliable. Understanding the mechanisms involved in ovarian cancer development and growth will allow opportunities for the rational design of effective anti-tumor treatment modalities. More objective and reproducible prognostic variables will improve the predictiveness of prognosis [37]. To date, there are no prognostic factors in ovarian cancer that adequately account for tumor biology and the course of the disease. In recent years, some reports have described the prognostic significance of the amplification and over-expression of the oncogene c-erbB-2 (HER2/neu) in various human cancers, including ovarian cancer. As we have seen, the c-erbB-2 proto-oncogene is located on the long arm of chromosome 17. It encodes a 185 kD trans-membrane glycoprotein receptor (p185HER2) that has sequence similarities with the EGFR. In ovarian cancer, the percentage of c-erbB-2 positive cases varies from 9% to 32%. Correlation with tumor stage and the degree of histological differentiation was not observed. The over-expression of c-erbB-2 is a new and statistically independent prognostic factor. The over-

expression of oncogene c-erbB-2 in ovarian cancer can be detected by IHC staining for the protein p185 and characterizes a group with unfavorable tumor biology and a significantly worse prognosis. Elevated serum levels of the c-erbB-2 oncoprotein have been identified in patients with various cancers known to overexpress the c-erbB-2 oncogene. Antiproliferative effects of monoclonal antibodies directed against p185 have been demonstrated in breast cancer patients. This may lead to a new approach in ovarian carcinoma therapy too, over and above the diagnostic aspects [38]. Within past years, the measurement of serological, histochemical, and molecular genetic markers has had an increasing influence on clinical decisions about initial treatment and follow-up. The most studied and interesting markers in ovarian cancer, CA-125, CA-19.9, tumor-associated trypsin inhibitor (TATI), cancer associated serum antigen (CASA), CEA, tissue polypeptide antigen (TPA), tissue polypeptide specific antigen (TPS), and cytokeratin-19 fragment (CYFRA21-1) are now the most widely used serological tumor markers for management of ovarian cancer patients. Ras oncogenes, C-erb2 proto-oncogene, p53 suppressor gene, and B-cell lymphoma 2 (bcl-2) oncogene are examples of currently used molecular genetic markers. As histochemical markers-proliferation markers, flow cytometric analysis, thymidine labeling index, Ki-67 nuclear antigen or differentiation markers are nowadays the ones most often determined. Some of these markers might be useful adjuncts for monitoring response to therapy, including early detection of tumor reactivation to allow curative therapy and rapid detection of treatment failure. The study of these markers may also lead to a better understanding of the biological characteristics of ovarian cancer. Numerous tumor markers have been recognized as promising prognostic factors. The information derived from studies of these markers also represents the most promising avenue towards new treatment strategies. Nevertheless, to validate these factors, prospective studies of a large patient population are needed [39].

The biology of ovarian cancer covers essentially all aspects of the disease: from how it arises to how it responds to chemotherapy, often becomes refractory to treatment, and ultimately kills the patient. Ovarian cancer is often initially responsive to chemotherapy but ultimately becomes refractory [40]. Previous studies have suggested the safety of conservative surgery with unilateral salpingo-oophorectomy or cystectomy for patients with stage I borderline ovarian tumors. Laparoscopic treatment of adnexal masses has proved to be a safe and effective diagnostic and therapeutic tool in the hands of experienced laparoscopists. For women who are treated conservatively, follow-up is important. Surgery remains the most effective therapy for later stage lesions. Adjuvant therapy for advanced stage of borderline ovarian tumors remains controversial. Conservative management of borderline ovarian tumors is an appropriate therapeutic option for young women with early-stage lesions who wish to preserve their childbearing potential. Available data indicate that in these patients fertility, pregnancy outcome, and survival remain excellent [41]. Conventional therapy for epithelial ovarian cancer, including aggressive cytoreductive surgery followed by combination chemotherapy regimens, has failed to reduce the number of deaths caused by this disease, which remains the most lethal of gynecologic malignancies [42]. Surgery has reached its limits, and further aggressive surgery will result in an inordinate morbidity and mortality. Ovarian carcinoma is ideally treated by complete surgical removal of the cancer, followed by anti-cancer chemotherapy. Since it is often impossible to remove all of the cancer, adjunctive chemotherapy is playing an increasingly important role in the management of the cancer [43].

Drug discovery in the ovarian cancer arena has led to the activation of several important clinical trials. Many biologic agents have come down the pipeline and are being studied in

phase II trials for recurrent disease. These agents include anti-vascular compounds that disrupt angiogenesis through a variety of mechanisms (e.g., prevention of ligand-binding to the VEGF receptor-2 (VEGF-R2), high-affinity VEGF blockade, oral TKI stimulated by VEGF, inhibition of $\alpha 5 \beta 1$ integrin, neutralization of angioproteins, etc.). Other novel drugs include oral platinum compounds as well as those that antagonize the tumor proliferation genes in the Hedgehog pathway, and that target folic acid receptors which are expressed by ovarian cancer cells. In addition, studies are underway with oral agents that inhibit the TK activity associated with two oncogenes (EGFR and HER-2/neu). Finally, emerging technologies in clinical trials include nanotechnology to enhance delivery of chemotherapy to ovarian tumors, drug resistance/sensitivity assays to guide therapy, and agents that mobilize and induce proliferation of hematopoietic progenitor cells to aid in red blood cell, white blood cell, and platelet recovery following chemotherapy [44]. Monoclonal antibodies, which offer the promise of high selectivity for detection and therapy, may be targeted to tumor-associated antigens, GF, receptors, or oncogenes. They may be used alone as immunotherapeutic agents or conjugated to chemotherapeutic drugs, toxins, or radionuclides. Radioimmunoconjugates may also be used for preoperative or intraoperative tumor localization [42]. New anti-cancer drugs must be found or synthesized, and new combinations of current anti-cancer drugs with mechanisms to protect the bone marrow must be explored. The field of genetics and the identification of the patient at high risk because of a familial history of ovarian cancer must be expanded. The role of tumor markers and oncogenes requires more in-depth study so that these signs can play a greater role in monitoring and identifying the patient with early ovarian cancer. The emerging fields of genetic engineering and biologic response modifiers are opening up new avenues for additional modalities of therapy. The expanding areas of research in cancer are starting to dispel the doom and gloom of the last five decades with a spirit of optimism for the diagnosis and treatment of ovarian cancer [43].

In summary, ovarian cancer of epithelial origin is associated with the highest mortality rate of all gynecologic malignancies. Since no symptoms or signs are manifested at the early stages of the disease, it is no surprise that in 75% of patients peritoneal metastases are found during primary surgery. Despite advances in conservative treatment methods (invasive and non-invasive), screening for early detection of the disease is not yet available, and the overall survival rate is as low as 5-15%. Recent studies in molecular biology have drawn attention to different research directions in ovarian cancer and have contributed much to our understanding of this disease and its underlying pathologic mechanisms. Some of the new aspects of this research are, specifically: hereditary ovarian cancer, genetic background in terms of chromosomal changes, DNA anomalies, oncogenes, TSG, peptide GF and cytokines, invasiveness and metastasis, and finally, drug resistance. No breakthrough has as yet occurred in any of these subjects, but results are promising. The clinical application of the steadily increasing knowledge in the biology of ovarian cancer may assist in the development of new treatment modalities that will improve survival [45]. Significant progress has been made in understanding the molecular biology of ovarian cancer and the role that single-nucleotide polymorphisms, TSG, and oncogenes play in promoting tumor cell growth and proliferation. Strategies have been developed to correct gene defects or single out ovarian cancer cells for destruction. Molecular-based therapies are now under development to specifically target receptors and signal transduction pathways that control cell proliferation and apoptosis, angiogenesis, cellular adhesion, and cell motility in ovarian tumors. The end product of this

intense investigation will be new targeted therapies that offer the hope of improving the medical management of ovarian cancer while being significantly less toxic to normal cells [46].

Endometrial Cancer

Endometrial carcinoma is today among the most common malignancies of the female genital tract in industrialized countries, with a lifetime risk among women of 2-3%, and occurs predominantly after the menopause. Recently, the prolonged life expectancy, post-menopausal use of HRT, and the availability of easily applied diagnostic techniques have led to increasing incidence of endometrial cancer. Although during the past several decades, the histopathology, spread patterns, and prognostic factors of endometrial cancers have been better defined, the clinic-pathologic and biologic prognostic parameters should be further evaluated for the better treatment results in endometrial cancer [47]. In order to improve the treatment and follow-up of these patients, various prognostic factors have been extensively studied. Patient age, stage of disease, histologic type, and histologic grade have been shown to influence survival significantly, and the prognostic impact of these traditional clinic-pathologic variables is well established. In addition, parity, hormone receptor concentration in the tumor, DNA ploidy, and morphometric nuclear grade have all been found to influence prognosis. Information about DNA ploidy has especially been used in the clinical situation to determine individualized treatment. Several prognostic markers for tumor cell proliferation, cell cycle regulation (p53, p21, and p16), and angiogenesis have been identified. It is likely that the information derived from these tumor biomarkers will reduce the need for extensive surgical staging and adjuvant treatment in endometrial carcinoma [48].

Approximately 75% of cases are diagnosed at an early stage with a tumor confined to the uterine corpus. Although most patients are cured by surgery alone, about 15-20% with no signs of locally advanced or metastatic disease at primary treatment recurs, with limited responsiveness to systemic therapy. The most common basis for determining the risk of recurrent disease has been classification of endometrial cancers into two subtypes [49]. Increasing evidence, in fact, suggests that the majority of cases can be divided into two different types of endometrial cancer based on clinic-pathological and molecular characteristics. Type I, associated with an endocrine milieu of estrogen predominance, accounts for the majority of cases and is associated with a low-stage, low-grade and endometrioid histology and develop from endometrial hyperplasia. They have good prognosis and are sensitive to endocrine treatment. In contrast, type II endometrial cancers are not associated with a history of unopposed estrogens and develop from the atrophic endometrium of elderly women, are characterized by a high-stage, high-grade and non-endometrioid histology. Mainly, they are of serous papillary or clear cell morphology, have a poor prognosis and do not react to endocrine treatment. However, the prognostic value of this distinction is limited, as up to 20% of type I endometrial cancers recur, while half of type II cancers do not [50]. Both types of endometrial cancer probably differ markedly with regard to the molecular mechanisms of transformation. The transition from normal endometrium to a malignant tumor is thought to involve a stepwise accumulation of alterations in cellular mechanisms leading to dysfunctional cell growth [49].

Molecular techniques have been used to identify specific genetic alterations in endometrial cancers. Overexpression of the HER-2/neu oncogene occurs in 10% of endometrial cancers and correlates with poor survival. Alterations in other TKR (c-fms and EGFR) also occur in some

cases. The c-myc oncogene, which encodes a nuclear transcription factor, also may be over-expressed in some invasive cancers. Mutations in the K-ras oncogene occur in 10% and in 20-30% of American and Japanese endometrial cancers, respectively. K-ras mutations also have been observed in endometrial hyperplasias, and this may represent an early event in the development of some cancers. Mutation of the p53 TSG, with resultant over-expression of mutant p53 protein, occurs in 20% of endometrial adenocarcinomas. Over-expression of p53 is associated with advanced stage and poor survival. Because p53 mutations do not occur frequently in endometrial hyperplasias, this may be a relatively late event in endometrial carcinogenesis. Recent studies have shown that mutations occur in microsatellite sequences in some endometrial cancers. Because microsatellite instability in HNPCC has been found to be caused by mutations in DNA repair genes, similar mutations are being sought in endometrial cancers. Although several molecular alterations have been identified, the molecular pathogenesis of endometrial cancer remains poorly understood [51]. Some endometrial cancers and endometrial adenocarcinoma cell lines show amplified expression of proto-oncogenes (fos, fms, myc, myb, neu, and erb-B) and augmented production of GF (CSF-1), EGF, TGF-alpha, and TGF-beta), and EGFR. Oncogene expression, the presence of ER and PgR, and the fraction of cells in S phase are useful biochemical prognostic indicators of clinical outcome, and markers recognized by monoclonal antibodies are available for use in following the clinical course of the disease and responses to treatment. In vivo and in vitro studies on normal and neoplastic tissues are providing evidence of paracrine influences on epithelial cell proliferation. Long-term administration of tamoxifen as adjuvant therapy for breast cancer has recently been found to increase the risk for development of endometrial cancer [52].

Uterine cancer is often diagnosed at an early stage and is therefore considered one of the most curable gynecologic malignancies. Despite this, a substantial number of women who present at more advanced stage or with unfavorable histologies suffer significant morbidity and death from this disease. Research continues along several fronts in an attempt to improve the prognosis for this group of women. Basic scientific research has continued to evaluate mechanisms of carcinogenesis in the hope that better targets for treatment and prevention of disease will be found. Epidemiologic studies have attempted to further define risk factors as well as elucidate risk in those patients receiving combination estrogen and progestin HRT. Clinical studies have further defined prognostic factors, and examined new surgical staging techniques and the need for adjuvant therapy after primary surgery. However, treatment options for advanced and recurrent disease remain limited [53, 54].

In summary, adenocarcinoma of the endometrium is the most common gynecologic malignancy in the United States, accounting for some 36,000 cases of invasive cancer each year. Although most endometrial carcinomas are detected at low stage, there is still a significant mortality from the disease. Hyperplastic lesions of the endometrium follow a continuum, with the risk of progression to carcinoma being related to the severity of the disorder. Risk factors associated with the development of adenocarcinoma include hyperplasia, obesity, menstrual abnormalities, diabetes, hypertension, prior pelvic irradiation, sequential oral contraceptive (OC) use, diet, and exogenous estrogen use. In post-menopausal women, prolonged life expectancy, changes in reproductive behavior and prevalence of overweight and obesity, as well as HRT use, may partially account for the observed increases of incidence rates in some countries. There is also some evidence of genetic predisposition, and some data indicating the possibility of specific genetic abnormalities and activation of oncogenes as factors determining the etiology of the disease. At this time there is no accepted screening test for endometrial

carcinoma, though the role of immunochemistry techniques for screening and follow-up has just begun to be realized. Dilatation and curettage (DandC) along with hysteroscopy remain the major means of diagnosis. In order to improve treatment and follow-up of endometrial carcinoma patients, the importance of various prognostic factors has been extensively studied. A variety of prognostic variables including tumor cell type (serous carcinoma and clear cell carcinomas [CCC] are poor prognostic types), histological grade, stage of disease, depth of myometrial invasion, lymph node status, peritoneal cytology, presence of disease in preformed vascular spaces, presence of adnexal metastases, lymphovascular space involvement, and presence of cervical involvement have been defined. Other factors currently being investigated are ER and PgR status, p53 status, flow cytometric analysis for ploidy and S-phase fraction, and oncogenes such as HER-2/neu (c-erbB-2). The identification of high-risk groups would make it possible to avoid unnecessary adjuvant treatment among patients with a good prognosis. Although the treatment plan for each patient must be individualized, the mainstay of treatment remains total abdominal hysterectomy with bilateral salpingo-oophorectomy. Metastatic and recurrent disease is usually treated with hormonal therapy and systemic chemotherapy. Radiation therapy like surgery in recurrent disease is only applicable for the treatment of local recurrences [55, 56].

Cervical Cancer

Cervical carcinoma is one of the major causes of death in women worldwide. It is difficult to foresee a dramatic increase in cure rate even with the most optimal combination of cytotoxic drugs, surgery, and radiation. Therefore, testing of molecular targeted therapies against this malignancy is highly desirable. Cervical cancer is a multistep process with accumulation of genetic and epigenetic alterations in regulatory genes, leading to activation of oncogenes and inactivation or loss of TSG. In the last decade, in addition to genetic alterations, epigenetic inactivation of TSG by promoter hypermethylation has been recognized as an important and alternative mechanism in tumorigenesis. In cervical cancer, epigenetic alterations can affect the expression of HPV as well as host genes in relation to stages representing the multistep process of carcinogenesis [57]. Significant advances have been made toward the understanding of the initiation and progression of cervical dysplasia and neoplasia at the molecular level. To date, this has not translated into improvements in diagnosis or treatment although it is a realistic expectation that this will occur. Significant variation in the proportion of tissue specimens that exhibit genetic alterations is striking. This may be attributed to different methods of analysis, different methods of tissue fixation, which influence antigen preservation, and the analysis of small numbers of samples per report, which introduces the possibility of sampling error. In spite of the variation among published reports, it is clear that several genetic alterations occur in pre-neoplastic and early-stage invasive cervical neoplasms. The prognostic applicability of oncogene mutations is a particularly interesting area of investigation that is the closest to clinical application, although additional research involving larger numbers of patients is critical. The development of convenient methods of tissue fixation that preserve the myc oncoprotein, the synthesis of specific antibodies that provide consistent results, and the application of computer-assisted image analysis to quantitate results will be particularly important in this regard [58].

Invasive cervical cancer remains a leading cause of morbidity and mortality, especially among women in the developing world where screening is either deficient or absent. Of all agents linked to the causation of this disease, high-risk HPV appears to be the strongest factor. However, not all women with HPV develop cervical cancer. Steroid contraception has been postulated to be one mechanism whereby HPV exerts its tumorigenic effect on cervical tissue. Steroids are thought to bind to specific DNA sequences within transcriptional regulatory regions on the HPV DNA to either increase or suppress transcription of various genes. Although some earlier studies were reassuring as no increased incidence of cervical cancer was observed, subsequent research has shown a causative association, especially among long-term users. The role of steroids was further enhanced by the discovery of hormone receptors in cervical tissue. Some earlier studies of OC steroids found no increased risk, even after controlling for other risk factors, including smoking and number of partners. However, prospective studies have shown a greater progression of dysplasia to CIS with more than 6 years of steroid OC use. Similar findings were also evident from other work, including the Royal College of General Practitioners (RCGP) Oral Contraception Study. The World Health Organization (WHO) Collaborative Study of Neoplasia and Steroid Contraceptives showed a relative risk of 1.2 for invasive cancer in users of the long-acting progestational contraceptive, depot-medroxyprogesterone acetate (DMPA). However, in users of more than 5 years duration, an estimate of 2.4 was reported. The upstream regulatory region (URR) of the HPV type 16 viral genome mediates transcriptional control of the HPV genome and is thought to contain enhancer elements that are activated by steroid hormones. It has been shown that steroid hormones bind to specific glucocorticoid-response elements within HPV DNA. Experimental evidence has revealed that high-risk type HPV 16 are able to stimulate the development of vaginal and cervical squamous cell carcinomas (SCC) in transgenic mice exposed to slow-release pellets of 17 beta-estradiol (E2) in the presence of human keratin-14 promoter. SCC developed in a multi-stage pathway only in transgenic mice and not in non-transgenic mice. The E6 oncoprotein of HPV 16 has been shown to bind to the p53 TSG and stimulate its degradation by a ubiquitin-dependent protease system. Steroid hormones are thought to increase the expression of the E6 and E7 HPV 16 oncogenes, which in turn bind to and degrade the p53 gene product, leading to apoptotic failure and carcinogenesis. However, the molecular basis of this remains to be proven [59]. The mere presence of the HPV is not sufficient for the development of neoplasia. Genetic and other co-factors seem to be necessary for the expression of the invasive phenotype. The expression of HPV 16 E6-E7 oncogenes results in chromosomal aneuploidy, favoring the integration of high-risk HPV genomes into cellular chromosomes. The integration of HPV 16 may not always be required for the progression to the invasive phenotype, unlike HPV 18 DNA. Such integration sites are randomly distributed over the whole genome. The genetic susceptibility of codon 98 of the fragile histidine triad has been elucidated. The interaction between Human Immunodeficiency Virus (HIV) and HPV are complex and favor the persistence and progression of cervical disease. Future research should pave the way for therapeutic vaccine development [60].

Gestational Trophoblastic Disease

Gestational trophoblastic diseases (GTD) are interrelated conditions characterized by abnormal growth of chorionic tissues with various propensities for local invasion and

metastasis. Complete mole seems to be more like choriocarcinoma and is a unique conception in that all nuclear DNA is paternally derived and all cytoplasmic DNA is maternally derived. In contrast, partial mole generally appears to be more like normal placenta and has a triploid karyotype, where the extra haploid set of chromosomes is paternally derived: GTD are characterized by altered expression of several regulatory GF and oncogenes. These results may have both prognostic and therapeutic consequences and provide insight into the relationship between normal placenta and gestational trophoblastic diseases. While differences in expression of oncoproteins may be important to the development of GTD, the precise molecular changes that are critical to pathogenesis remain unknown [61, 62]. Tumour invasion and trophoblastic invasion share the same biochemical mediators: the MMP and their inhibitors (tissue inhibitor of metalloproteinases [TIMP]). MMP are a family of enzymes capable of digesting the extracellular matrices of the host tissues. Human cytotrophoblastic cells are constitutively invasive and produce MMP. That MMP are causally related to trophoblast invasion in the endometrium is shown by the fact that TIMP inhibit cytotrophoblastic invasion in vitro. In contrast to tumor invasion of a host tissue, trophoblastic invasion during implantation and placentation is stringently controlled both in space and time. The factors responsible for these important regulatory processes are unknown, but in-vitro studies point to autocrine (trophoblastic) and paracrine (endometrial) controls by cytokines and GF. These regulators exert their effects directly or indirectly by activating nuclear transcription factors. Transcription factors are proteins or protein complexes (often the products of oncogenes) that activate genes by binding to specific sites of the DNA located in the regulatory (5' flanking) region of genes. Some authors have speculated about a potential role of these transcription factors (particularly the oncogenes Jun and Fos) in regulating trophoblast invasion [63, 64].

Oncogenes and Cancer Therapy

In the past few years, many encouraging advancements have been made in understanding the molecular mechanisms underlying carcinogenesis and tumor progression. These improvements have led to the identification of promising new targets for cancer therapy [21]. Antisense technology has emerged as an exciting and promising strategy in the fight against cancer. The antisense concept is to selectively bind short, modified DNA or RNA molecules to mRNA in cells and prevent the synthesis of the encoded protein. As anticancer agents, these molecules can be targeted against a myriad of genes involved in cell transformation, cell survival, metastasis, and angiogenesis. Indeed, the list of possible antisense targets increases as the knowledge of the genetic basis of oncogenesis expands. Antisense cancer drugs have entered human clinical trials. At least four of these compounds are currently in phase II trials, including those targeting PKC alpha, bcl-2, c-raf, and the R1-alpha subunit of PKA. A new development in antisense chemistry (peptide nucleic acids) is achieved, along with alternative antisense-related strategies (ribozymes and 2-5A-antisense) designed to overcome some of the challenges of this already encouraging technology [65].

Heparin-binding (HB)-EGF, a member of the EGF family, exerts its biological activity through activation of the EGFR and other erbB receptors. HB-EGF participates in diverse biological processes, including heart development and maintenance, skin wound healing, eyelid formation, blastocyst implantation, progression of atherosclerosis, and tumor formation, through the activation of signaling molecules downstream of erbB receptors and interactions

with molecules associated with HB-EGF. Recent studies have indicated that HB-EGF gene expression is significantly elevated in many human cancers and its expression level in a number of cancer-derived cell lines is much higher than those of other EGFR ligands. Several lines of evidence have indicated that HB-EGF plays a key role in the acquisition of malignant phenotypes, such as tumorigenicity, invasion, metastasis, and resistance to chemotherapy. Studies *in vitro* and *in vivo* have indicated that HB-EGF expression is essential for tumor formation of cancer-derived cell lines. CRM197, a specific inhibitor of HB-EGF, and an antibody against HB-EGF are both able to inhibit tumor growth in nude mice. These results indicate that HB-EGF is a promising target for cancer therapy, and that the development of targeting tools against HB-EGF could represent a novel type of therapeutic strategy, as an alternative to targeting *erbB* receptors [66].

ONCOGENES IN REPRODUCTIVE ENDOCRINOLOGY

The union of a healthy egg and a healthy sperm is required for propagation of mammalian species, and thus any factor that disrupts the normal production of female or male gametes is a potential threat to reproductive performance. These hazards to gonadal function are derived from both clinical and environmental sources, and can affect either somatic cell or germ cell lineages, or in some cases both, with equal consequences, i.e., the loss of fertility. Females of the species are particularly at risk to gonadal toxicants since, unlike males, females are born with an irreplaceable stockpile of germ cells in their ovaries at the time of birth. Natural selection processes further dwindle this precious reserve such that by the time of puberty, when eggs could actually be used for fertilization and pregnancy, the number of remaining oocytes has been depleted to less than three-quarters of the starting cohort. In the human female, this completely normal loss of oocytes eventually leads to near-exhaustion of the germ cell reserve around the fifth decade of life, and the menopause ensues. Consequently, exposure of women to potentially damaging agents, such as anti-cancer drugs, industrial chemicals, or even cigarette smoke, can have a dramatic and irreparable effect on the ovary by accelerating the natural process of germ cell depletion and, as a direct consequence, advance the time to menopause. Many gonadal toxicants exert their effects via modulation of discrete signaling pathways linked to apoptotic cell death in the female germ-line [67]. For decades, the mechanisms responsible for germ cell depletion from the ovary, either directly during the perinatal period or indirectly via follicular atresia during post-natal life, have remained relatively obscure. The recent application of sensitive biochemical techniques for the study of cell death to the analysis of ovarian function has revealed that these two events, as well as a third instance of ovarian cell degeneration (luteolysis), are dependent upon the activation of physiological cell death mechanisms. It is therefore hypothesized that the controlled deletion of ovarian cell populations is accomplished via activation of a “universal” pathway of cellular suicide involving altered expression of a conserved cohort of genes [68]. Apoptosis is a process of single-cell deletion requiring active participation of the cell in its own demise. First described in 1972, it is now known to play a major role in embryogenesis, tissue homeostasis, and neoplasia. Apoptosis can be initiated when DNA damage occurs causing the cell to pause in its reproductive cycle. If the DNA damage is beyond repair, the cell proceeds to apoptotic cell death. When the genetic mechanism involved in the pathway of apoptosis is altered, the cell

does not die. Further mutations occur by proliferation and such multiple mutational events can lead to a malignant phenotype and cancer growth. The TSG p53 causes a DNA-damaged cell to rest and attempt repair. If damage is irreparable, p53 levels will continue to increase, initiating apoptosis. Mutation of p53, found in approximately 50% of cancers, can stop the apoptotic process. Increased bcl-2 expression, an apoptosis inhibitor, also plays a role in cellular transformation and cancer growth. Its altered expression occurs in the presence of oncogene expression. Apoptosis has a role in malignant transformation, cancer growth, and response to therapy for gynecological cancers. For cervical cancer and its precursors, data on apoptotic index, bcl-2, and Bax expression have a relationship to HPV expression. In ovarian epithelial malignancies, apoptosis plays a role in chemotherapeutic responses. The data for endometrial cancer are currently limited to apoptotic index [69].

Through the study of naturally occurring mutations in humans, the creation of mutations by site-directed mutagenesis, and the production of transgenic knockout mice, further understanding of molecular reproductive endocrinology had been achieved. Mutations in the aromatase gene in females have confirmed that its deficiency results in a previously unrecognized form of sexual ambiguity with a 46,XX karyotype, and delayed puberty with multicystic ovaries. It has long been known that estrogen is necessary for skeletal growth and epiphyseal closure in the female, but aromatase and ER gene mutations in men have demonstrated for the first time, that estrogen is important for epiphyseal closure in the male. Mutations in the steroidogenic acute regulatory protein have been recently described that demonstrate the cause for lipoid congenital adrenal hyperplasia, a disorder characterized by the complete lack of steroid production. New gene mutations in human chorionic gonadotropin beta-subunits (beta-hCG), pituitary hormones, G-protein coupled receptors, G-proteins, steroid enzymes and their receptors have also been characterized recently. Site-directed mutagenesis experiments and transgenic knockout mice have been increasingly used to study the effects of normal endocrine function. Normal functions of steroid receptor genes (steroidogenic factor-1, ER, Pgr), the glycoprotein alpha-subunit, luteinizing hormone (LH) beta, and proto-oncogenes such as rearranged during transfection (RET) have been better characterized by creating knockout models. Molecular biology techniques permit these types of studies which may be difficult, if not impossible, to perform otherwise in physiologic settings [70, 71].

E2 and ER signaling have been implicated in the development and progression of several cancers. Emerging evidence suggests that the status of ER co-regulators in tumor cells plays an important role in hormonal responsiveness and tumor progression. Proline, glutamic acid, and leucine-rich protein-1 (PELP1), also known as modulator of non-genomic actions of the ER (MNAR), a novel ER co-activator that plays an essential role in the ER's actions and its expression, is de-regulated in several hormonal responsive cancers, including breast, endometrial, prostate, and ovarian cancer. The precise function of PELP1/MNAR in cancer progression remains unclear, but PELP1 appears to function as a scaffolding protein, coupling ER with several proteins that are implicated in oncogenesis. Emerging evidence suggests that PELP1/MNAR increases E2-mediated cell proliferation and participates in E2-mediated tumorigenesis and metastasis [72]. PELP1 has been shown to participate in both genomic and non-genomic functions of ER. The expression and localization of PELP1/MNAR are deregulated in a wide variety of tumors and have been implicated in the development of hormonal resistance in cancer cell lines. Emerging data suggest that PELP1/MNAR interacts with many proteins and activates several oncogenes, including Src kinase, PI3K, and signal

transducers and activators of transcription 3 (STAT3). These new results suggest that PELP1/MNAR may act as an oncogene as well as cooperating with other oncogenes [73, 74].

The skin expresses ER, PgR, and androgen receptors (AR). In the presence of steroid hormones, such as those contained in OC, the skin likely responds to hormonal signals that control the cell cycle, apoptosis, DNA replication, and other cellular functions. Some estrogen-responsive pathways have the potential to promote tumor development, including the augmentation of EGF signaling, the expression of proto-oncogenes, and inhibition of apoptosis. The question of whether OC increase the risk for the development of skin cancer, particularly melanoma, is still an area of concern. The available evidence suggests that while the skin responds to estrogens, progestins, and androgens, these responses do not significantly increase the risk of developing skin cancer when estrogen exposure is not excessive [75].

Endometriosis

Endometriosis, a disease affecting 3% to 10% of women in the reproductive-age group, is one of the most frequent benign gynecological diseases, with an unclear pathophysiology characterized by the ectopic growth of endometrial tissue under the influence of estrogen causing endometrium-like inflammatory lesions outside the uterine cavity. It is also becoming recognized as a condition in which ectopic endometrial cells exhibit abnormal proliferative and apoptotic regulation in response to appropriate stimuli. Apoptosis plays a critical role in maintaining tissue homeostasis and represents a normal function to eliminate excess or dysfunctional cells. Accumulated evidence suggests that, in healthy women, endometrial cells expelled during menstruation do not survive in ectopic locations because of programmed cell death, while decreased apoptosis may lead to the ectopic survival and implantation of these cells, resulting in the development of endometriosis. Both the inability of endometrial cells to transmit a “death” signal and the ability of endometrial cells to avoid cell death have been associated with increased expression of anti-apoptotic factors and decreased expression of pre-apoptotic factors. Further investigations may elucidate the role of apoptosis-associated molecules in the pathogenesis of endometriosis. Medical treatment with apoptosis-inducing agents may be novel and promising therapeutic strategy for endometriosis [76].

Endometriosis is well established as a condition showing heritable tendencies. Polygenic/multi-factorial etiology appears far more likely to be the etiology than Mendelian inheritance. The current task is to determine the number and location of genes responsible for endometriosis. Endometriosis is a genetic disorder of polygenic/multi-factorial inheritance and bears similarity to neoplasia and, hence, is a multistep phenomenon of clonal origin [77]. Recently, a number of studies have investigated genetic polymorphisms as a possible factor contributing to the development of endometriosis. Current data regarding genes with nucleotide polymorphisms investigated with regard to endometriosis found a strikingly large amount of conflicting results. About 50% of the reviewed studies demonstrated positive correlations between different polymorphisms and endometriosis. This relation is most clearly seen in groups 1 (cytokines and inflammation), 2 (steroid-synthesizing enzymes and detoxifying enzymes and receptors), 4 (estradiol metabolism), 5 (other enzymes and metabolic systems), and 7 (adhesion molecules and matrix enzymes). Group 8 (apoptosis, cell-cycle regulation, and oncogenes) seemed to be negatively correlated with the disease, whereas group 3 (hormone receptors), 6 (GF systems), and especially 9 (human leukocyte antigen [HLA] system

components) showed a relatively strong correlation. Polymorphisms may have a limited value in assessing possible development of endometriosis. There are some single nucleotide polymorphisms (SNP) relationships that are clinically stronger than others [78]. In a series of studies, it has been hypothesized that endometriotic proliferation is, in part, precipitated by mutations in oncogenes or deletions in TSG that have been shown to be important steps in the transformation from a benign to a malignant epithelium. It has been reported previously that no mutations in the p53 and k-ras genes in cases of endometriosis were found. However, having shown that endometriotic deposits were monoclonal, some authors showed loss of heterozygosity on chromosomes 9p (18%), 11q (18%), and 22q (15%); in total 28% of endometriotic lesions showed loss of heterozygosity at one or more sites. Any loss of heterozygosity in normal endometrium could be demonstrated. Adjacent endometriosis, atypical endometriosis, and EAC of the ovary have been examined and showed common genetic alterations that are consistent with a common lineage. These common alterations were not seen in lesions that were distant from each other. In EAC, an increased frequency of mutations in the PTEN/methylmalonic aciduria cobalamin deficiency (MMAC) TSG has been reported that was not seen in CCC or serous carcinoma, suggesting distinct developmental pathways for these tumors [79]. Similarly to tumor metastasis, endometriotic implants require neo-vascularization to proliferate, invade the extracellular matrix, and establish an endometriotic lesion. Despite its high prevalence and incapacitating symptoms, the exact pathogenic mechanism of endometriosis remains unsolved. A relationship between endometriosis and gynecological cancer, especially ovarian cancer, has been reported. Endometriosis is a multifactorial and polygenic disease, and emerging data provide evidence that a dysregulation of miRNA expression may be involved. miRNA appear to be potent regulators of gene expression in endometriosis, raising the prospect of using miRNA as biomarkers and therapeutic tools in this disease [11].

There is evidence that endometriosis, as well as drugs used in the process of in vitro fertilization (IVF), appear to associate with increased risk for gynecological cancer. There are data to support that ovarian endometriosis could have the potential for malignant transformation. Epidemiologic and genetic studies support this notion. It seems that endometriosis is associated with specific types of ovarian cancer (EAC and CCC). There is no clear association between endometriosis and breast or endometrial cancer. More studies are needed to establish the risk factors that may lead to malignant transformation of this condition and to identify predisposed individuals who may require closer surveillance. Currently, there is no proven relationship between any type of gynecological cancer and drugs used for infertility treatment. In principle, infertile women have increased risk for gynecologic malignancies. Nulligravidas who received treatment are at increased risk for malignancy compared with women who had conceived after treatment. There is limited evidence that clomiphene citrate use for more than six cycles or 900 mg or treatment of women over the age of 40 could increase their risk for ovarian and breast cancer. More studies with the appropriate statistical power and follow-up time are required to evaluate accurately the long-term effects of these drugs and procedures [80]. Thus, although population-based studies have unequivocally reported an increased risk of ovarian cancer in women with endometriosis, the biological evidence supporting the idea of endometriosis as a pre-neoplastic condition is scanty and not well substantiated. The fundamental features of human neoplasms (monoclonal growth, genetic changes, mutations in TSG and replicative advantage) have been evaluated in endometriotic lesions but results obtained are discordant. It is plausible that ectopic glands may

expand monoclonally but the entity of this phenomenon is debated. According to some allelotyping studies, from one-third to one-half of endometriosis lesions would harbor somatic genetic changes in chromosomal regions supposed to contain genes involved in ovarian tumorigenesis, especially for the endometrioid histotype. These findings would be consistent with the progression model for carcinogenesis from the benign precursor to ovarian cancer but they could not be unequivocally replicated. Gene mutational studies are rare in this context. A single group has found missense mutations and deletions of PTEN gene in about 20% of ovarian endometriotic cysts. Moreover, in a model of genetically engineered mice harboring an oncogenic allele of k-ras resulting in benign lesions reminiscent of endometriosis, a conditional deletion of PTEN caused the progression towards the EAC. Based on these data, the causal link between endometriosis and ovarian EAC/CCC remains to be defined both in terms of entity of association and of underlying molecular mechanisms [81]. In conclusion, although endometriosis generally remains a benign condition, it demonstrates somatically acquired genetic alterations. CCC and EAC are the most frequent types of epithelial ovarian carcinoma (EOC) associated with endometriosis. Retrograde menstruation or ovarian hemorrhage carries highly pro-oxidant factors, such as iron, into the peritoneal cavity or ovarian endometrioma. CCC and EAC should be considered separately in studies of endometriosis-associated EOC. The repeated events of hemorrhage in endometriosis can contribute to carcinogenesis and progression via three major processes:

- 1) increasing oxidative stress promotes DNA methylation;
- 2) activating anti-apoptotic pathways supports tumor promotion; and
- 3) aberrant expression of stress signaling pathways contributes to tumor progression [82, 83].

CONCLUSION

Improved molecular techniques have led to the identification of many genetic mutations in gynecologic malignancies [5]. In gynecologic oncologic fields, there are many investigations to explore the basic pathogenesis of gynecologic cancer, such as cervical cancer, ovarian cancer, and endometrial cancer. It is now known that specific types of human papilloma virus (HPV) are the principal etiologic agents for both cervical cancer and its precursors. However, the various kinds of alterations in oncogenes and tumor suppressor genes may play additional roles in carcinogenesis of cervical cancer. Although ovarian carcinoma is the most frequent cause of death from gynecologic malignancies, the histogenesis and biological characteristics of these tumors are not well understood. During the last several years, many key observations have been made concerning the genetic alterations associated with ovarian cancer. Recent researches including some dominant oncogenes and tumor suppressor gene mutations common to these malignancies are providing bases to elucidate the mechanisms underlying this cancer. The most important basis of endometrial cancer is that K-ras and p53 mutations are also frequently observed [1]. The molecular characterization of cancer has provided a better understanding of tumor formation and the clinical behavior of different tumor types, with important implications for developing screening tests and prognostic markers. Applications of these findings have led to novel targeted gene therapies that correct the critical genetic defects

seen in gynecologic cancers. Future research will focus on the clinical translation of these genetic alterations as targets of cancer prevention, screening, and treatment [5].

Chapter 102

**THE CLASSIFICATION, MECHANISMS
OF ACTIVATION AND ROLES IN CANCER
DEVELOPMENT OF ONCOGENES**

ABSTRACT

Cancer is an uncontrolled cell growth caused by accumulation of genetic and epigenetic mutations in genes that normally play a role in the regulation of cell proliferation, survival, apoptosis and cell cycle. Mutations are occurring mainly in oncogenes, tumor-suppressor genes, microRNA genes, or as DNA repair defects and aberrant DNA methylation. Oncogenes encode proteins that control cell proliferation and/or apoptosis. Products of oncogenes can be classified into 6 groups by its biological activity: transcription factors, growth factors, growth factor receptors, signal transducers, chromatin remodeling and apoptotic regulators. The main changes related to oncogene activation are chromosomal translocations and mutations that can occur as early events or during tumor progression; whereas amplification usually occurs during the tumor progression. These alterations are usually somatic events, although germ-line mutations can also predispose to familial cancer. A single genetic change is rarely insufficient for developing a malignant tumor. Most evidences point to a multistep process of sequential alterations in a wide number of oncogenes, tumor-suppressor genes, or microRNA genes related with cancer.

Recently, other mechanisms as the inflammation or alterations in the cellular metabolism have been associated with cancer. This chapter describes some of the key molecular mechanisms involved in the development and progression of cancer.

INTRODUCTION

During already long time, it has been accepted that the cancer is caused by the accumulation of genetic and epigenetic changes that lead to abnormal regulation of the cell growth control [1]. Discovery that abnormal genes, named oncogenes, play a crucial role in developing the malignant disease has been decisive in understanding the genetic nature of cancer. More recently, six biological capabilities acquired during the multistep development of human tumors were established as the principal hallmarks of cancer. These features rationalize the complexities of the neoplastic disease and comprise: sustaining proliferative signaling, evading growth suppressors, resisting cell death, enabling replicative immortality, inducing angiogenesis, and activating invasion and metastasis.

In addition, two essential components of the tumorigenic disease, which guides the tumor progress, are: genome instability, which generates the genetic diversity that accelerates the hallmarks acquisition, and inflammation, which promotes multiple hallmark functions. Two other emerging tumor features have been added recently: reprogramming of energy metabolism and the microRNA genes that can initiate tumorigenesis, enhance its progression and evade the immune destruction. Finally, neoplastic cells exhibit another type of complexity: a repertoire of recruited and apparently normal cells that contribute to create a “tumor microenvironment” [2-5]. Only the whole understanding of this biological complexity will permit us to develop more efficient cancer treatments. In this chapter we intend review the most important features related with the oncogenes, their activation mechanisms and roles in cancer, and the malignant metabolic reprogramming.

ONCOGENES

Are altered forms of normal cellular genes called proto-oncogenes. In human cancers, proto-oncogenes are frequently located adjacent to chromosomal breakpoints and are targets for mutation.

Products of proto-oncogenes are highly conserved in evolution and serve to regulate the cascade of events that maintains the ordered progression through the cell cycle, reproduction, and differentiation. In cancer cells, this ordered progression is partially lost when one or more of the components of this pathway are altered [6].

Our understanding of the molecular mechanisms leading to cancer has considerably advanced from the study of oncogenes. The application of techniques from many cancer research disciplines has led to the discovery of both dominantly acting transforming genes and of tumor suppressor genes [6].

Discovery of oncogenes. The majority of oncogenes were initially isolated as altered forms of proto-oncogenes acquired (transduced) by RNA tumor viruses (*v-onc*). In 1990, Payton Rous [7] discovered that transplantable sarcomas in chickens could be induced by a cell free agent. The transforming agent was a retrovirus that had transduced part of a normal cellular gene called *src* (sarcoma).

The virally transduced *src* gene (*v-src*) was altered by mutation compared with its normal cellular counterpart (*c-src*), rendering it constitutively activated. This discovery demonstrated

that our cells harbor genes that, when abnormally activated, are capable of inducing tumorigenesis [8, 9].

Over 70 proto-oncogenes activated by proviral insertion of a non-transforming retrovirus have been identified. This number includes some genes first identified as viral oncogenes [10-12].

Detection of oncogenes in human tumors. Evidence for a genetic role in cancer comes from multiple sources. Many of the cancer prone syndromes, such as Fanconi syndrome, Bloom syndrome, and ataxia telangiectasia, show greatly increased chromosome instability [13]. Studies of colon cancer demonstrate that many cancers have accumulated multiple chromosome deletions and mutations [14].

Identification that the bacterial *mutS* and *mutL* DNA mismatch repair genes as genetic lesions that predispose individuals to colon cancer further supports the role of mutation in the generation of cancer [15, 16].

Tumoral transformation. Transforming events in cancer development includes three stages: initiation, promotion and progression [17].

Table 1. Chromosome translocation in human cancers [1]

Affected gene	Rearrangements	Disease	Protein type
Oncogenes juxtaposed with IG loci			
c-MYC	t(8:14) (q24;q32) t(2:8) (p12;q24) t(8:22) (q24;q11)	Burkitt Lymphoma; BL-ALL	HLH domain
BCL1 (Cyclin D1)	t(11:14) (q13;q32)	B-cell chronic lymphocyte leukemia	PRADI-G1 Cyclin D1
BCL-2	t(14:18) (q32;q21)	Follicular Lymphoma	Inner mitochondrial membrane
BCL-3	t(14:19) (q32;q13.1)	Chronic B cell leukemia	CDC10 motif
IL-3	t(5:14) (q31;q32)	Acute pre-B cell leukemia	Growth factor
Oncogenes juxtaposed with TRC loci			
c-MYC	t(8:14) (q24;q11)	Acute T cell leukemia	HLH domain
LYLA	t(7:19) (q35;p13)	Acute T cell leukemia	HLH domain
TALI/SCL/TCL-5	t(1:14) (q32;q11)	Acute T cell leukemia	HLH domain
TAL-2	t(7:9) (q35;q34)	Acute T cell leukemia	HLH domain
Rhombotin 1/ttg-1	t(11:14) (p15;q11)	Acute T cell leukemia	HLH domain
Rhombotin 2/ttg-2	t(11:14)(p13;q11) t(7:11) (q35;p13)	Acute T cell leukemia	HLH domain
HOX11	t(10:14) (q24;q11)	Acute T cell leukemia	Homeodomain
TAN-1	t(7:9)(q34;q34.3)	Acute T cell leukemia	Notch homologue
TCL-1	t(14:14) (q11;q32.1), t(7q35-14q32.1) or inv14(q11;q32.1)	T- cell prolymphocytic leukemia	
Hematopoietic tumor			
Gene fusion			
c-ABL (9q34) BCR (22q11)	t(9:22) (q34;q11)	Chronic and acute myelogenous leukemia	Tyrosine Kinase activated by BCR
PBX-1 (1q23)	t(1:19) (q23;p13.3)	Acute pre-B cell leukemia	Homeodomain

Table 1. (Continued)

Affected gene	Rearrangements	Disease	Protein type
E2A (19p13.3)			HLH
PML(15q21)	t(15:27) (q21;q11-22)	Acute promyelocytic leukemia	Zn finger
RAR (17q21)			
CAN (6-23)	T(6:9) (p23;q34)	Acute myeloid leukemia	No homology
DEK (9q34)			
REL	Ins (2:12) (p11.2-14)	Non- Hodgkin lymphoma	NF-KB family
ALL1(MLL)*	11q23	ALL and AML	Chromatin modifiers
Solid tumors			
Gene fusions in sarcomas			
FL11, EWS	t(11:22) (q24; q12)	Ewing's sarcoma	Ets transcription factor family
ERG, EWS	t(21:22) (q22;q12)	Ewing's sarcoma	Ets transcription factor family
ATV1, EWS	t(7:21) (q22;q12)	Ewing's sarcoma	Ets transcription factor family
ATF1, EWS	t(12:22) (q13;q12)	Soft-tissue clear cell sarcoma	Transcription factor
CHN, EWS	t(9:22) (q22.31;q12)	Myxoid chondrosarcoma	Steroid receptor family
WT1,EWS	t(11:22) (p13;q12)	Desmoplastic small round cell tumor	Wilm's tumor gene
SSX1, SSX2, SYT	t(X:18) (p11.2;q11.2)	Synovial sarcoma	HLH domain
PAX3, FKHR	t(1:13) (q36;q14)	Alveolar	Homeobox homologue
PAX7, FKHR	t(1:13) (q36;q14)	Rhabdomyosarcoma	Homeobox homologue
CHOP, TLS	t(12:16) (q13;p11)	Myxoid liposarcoma	Transcription factor
var, HMG1-C	t(var:12) (var;q13-15)	Lipomas	HMG DNA binding protein
HMG2-C	t(12:14) (q13;q15)	Leiomyomas	HMG DNA binding protein
Gene fusions in thyroid carcinomas			
RET/ptc1	Inv(10) (q11.2;q2.1)	Papillary thyroid carcinomas	Tyrosine kinase activated by H4
Ret/ptc2	t(1:17) (q11.2;q23)	Papillary thyroid carcinomas	Tyrosine kinase activated by Rla (Pka)
RET/ptc3	Inv(10) (q11.2)	Papillary thyroid carcinomas	Tyrosine kinase activated by ELE1
TRK	Inv(1) (q31;q22-23)	Papillary thyroid carcinomas	Tyrosine kinase activated by TPM3
TRK-t1 (T2)	Inv(1) (q31;q25)	Papillary thyroid carcinomas	Tyrosine kinase activated by TPR
TRK-T3	T(1q31;3)	Papillary thyroid carcinomas	Tyrosine kinase activated by TFG
Gene fusions in prostate cancer			
TMPR552	ERG	T(21q22;21q22.3)	Ets transcription factor family activated by TMPR552
	ETV1	7p21.2	
Deregulation of oncogenes			
Parathyroid tumors			
PTH deregulates PRAD1 Cyclin D1	Inv(11) (p15q; q13)	Parathyroid adenoma	PRAD1/Cyclin D1
*ALL1 can fuse with more than 50 different genes. More frequently it fuses with AF4 in ALL and AF9 in AML.			

Oncogenes encode proteins that control cell proliferation, apoptosis or both and chromatin modification [1, 18]. They can be activated by chromosomal alterations resulting from mutation or gene fusion, by juxtaposition to enhancer elements, or by amplification. Genomic changes as chromosomal rearrangements, point mutations, deletions and gene amplification, activation of proto-oncogenes and inactivation of tumor suppressor genes are required for cancer initiation [19]. Amplification usually occurs during tumor progression [1, 20, 21].

Tissue specific mutations. Oncogene activation in human tumors is specific for some tissues; for example, gene amplification of *N-myc* occurs in neuroblastoma and small cell lung cancer but is extremely rare in other tissues; bcr-abl translocation is observed in most patients with chronic leukemia; mutations in the *RAS* gene are found in a high percentage of pancreatic, colorectal and lung cancers [22]. The activation of oncogenes by chromosomal rearrangements, mutations and gene amplification confers to the cells, carrying these alterations, greater growth and survival [1, 23].

Cytogenetic rearrangements. Chromosome abnormalities commonly found in cancer cells are inversions and translocations. In hematopoietic cancers and solid tumors, translocations and inversions deregulating the oncogenic transcription are present. In prostate cancer, the mechanism of oncogenic activation is a fusion between a gene with a very active promoter as *TMPRSS2*, and other with oncogenic activity as *ERG1* [24]. In cancers of T and B cells, the most common alterations giving *MYC* gene deregulation are translocations; while gene fusion is more common in myeloid cancers and soft tissue sarcomas [1]. Table 1 summarizes the most important chromosome abnormalities giving human cancer.

Oncogene response. After the oncogenic activation by mutations, the structure of the encoded protein enhances its transforming activity [25]. An example is the *RAS* oncogenes family: *KRAS*, *HRAS* and *NRAS*. Mutations in *RAS* genes has been associated with exposure to environmental carcinogens; when mutation occurs in codon 12, 13 or 61, the *RAS* gene encodes a protein which remains in the active state, so that induces continuous cell growth. *KRAS* mutations are common in carcinomas of the lung, colon and pancreas, whereas *NRAS* mutations occur primarily in acute myelogenous leukemia and myelodysplastic syndrome [1, 26].

Activating mutations in the *BRAF* gene occur in 59% of melanomas, 18% of colorectal cancers, 14% of hepatocellular carcinomas and 11% of gliomas [27]. Most *BRAF* mutations occur in the protein kinase domain by changing the valine residue to glutamic acid at position 599 (V599E), producing a protein with uncontrolled constitutive activity that stimulates the MAP kinase cascade, allowing proliferation, differentiation and cell survival [1, 27, 28]. Table 2 summarizes some oncogenes and tumor suppressors with their metabolic changes and related diseases.

Oncogene Classification

The products of oncogenes can be classified into six broad groups: growth factors, growth factor receptors, transcription factors, chromatin remodelers, signal transducers, and apoptosis regulators (Table 3).

Table 2. Biochemical functions of oncogenes and tumor suppressor genes [29]

Gene	Function	Disease
Oncogenes		
PI3K	Activates Akt (via PIP3); reduces β -oxidation (via Akt) enzyme carnitine palmitoyltransferase 1A (CPT1A)	Ovarian and gastrointestinal cancer
Akt	Upregulates fatty acid synthase (FASN); activates mTOR complex 1	Breast and ovarian cancer
Her2	Increases, through activation of PI3K, Akt, and mTOR expression of FASN and acetyl-CoA carboxylase α (ACC α) at the translational level	Mammary carcinoma
Tyrosine kinases	Generate phosphotyrosines that can bind to pyruvate kinase isoform PKM2, converting it from a tetramer to a less active dimer	Multiple cancers
E7 from HPV16	Binds PKM2, converting it from a tetramer to a less active dimer	Cervical carcinoma
Tumor Suppressor Genes		
p53	Required for expression of SCO2 and hence optimal OXPHOS; enhances the expression of TIGAR; as glycolysis inhibitor, reduces the expression of the glycolytic enzyme phosphoglyceromutase	Multiple cancers
VHL	Ubiquitin ligase required for degradation of HIF-1 α	Clear cell renal carcinoma
TSC1 (hamartin) and TSC2 (tuberin)	Negative regulators of Rheb (Which inhibit mTOR)	Tuberous sclerosis and lymphangioleiomyomatosis
PTEN	Negative regulator of class 1 PI3K	Cowden syndrome and prostate cancer
LKB1	Required for activation of AMPK	Peutz-Jeghers and sporadic lung adenocarcinoma
NF1	Negative regulator of RAS and PI3K-Akt pathway	Neurofibromatosis
PML	Negative regulator of mTOR complex 1	Promyelocytic leukemia and lung cancer
Succinate dehydrogenase (SDH). Subunits B,C and D.	Accumulated succinate competitively inhibits HIF-1 α prolylhydroxylases (PHDs)	Paraganglioma and pheochromocytoma.
Fumarate hydratase (fumarase)	Accumulated fumarate inhibits PHDs	Leiomyomatosis and papillary renal carcinoma

Growth Factors and Growth Factor Receptors

Activation of a single growth factor gene can result in malignant transformation. Platelet-derived growth factor (PDGF) is released from platelets during coagulation, induce proliferation of various cell types and stimulate fibroblasts to participate in wound healing [1, 30]. Over-expression of PDGF induces the *in vitro* transformation of fibroblasts containing

PDGF receptors, but it does not influence fibroblasts lacking these receptors [1]. This autocrine loop entails over-expression of *PDGF-β*, an antibody against its receptor, or small molecules that block the receptor and inhibit growth of the transformed fibroblasts.

Table 3. Classification of oncogenes [1]

Oncogene	Chromosome	Neoplasm	Mechanism of Activation
Transcription factors			
v-myc	8q24.1 (MYC)	Carcinoma myelocytomatosis	Deregulated activity
N-MYC	2p24	Neuroblastoma: lung carcinoma	Deregulated activity
L-MYC	1p32	Carcinoma of lung	Deregulated activity
v-myb	6q22-24	Myeloblastosis	Deregulated activity
v-fos	14q21-22	Osteosarcoma	Deregulated activity
v-jun	1p32-p31	Sarcoma	Deregulated activity
v-ski	1q22-24	Carcinoma	Deregulated activity
v-rel	2p12-14	Lymphatic leukemia	Mutant NFkappa B
v-est-1	11p23-24	Erythroblastosis	Deregulated activity
v-erbA1	17p11-21	Erythroblastosis	T3 transcription factors
v-erbA2	3p22-24.1	Erythroblastosis	T3 transcription factors
Related to apoptosis and others			
BCL2	18q21.3	B cell lymphomas	Antiapoptotic protein
MDM2	12q14	Sarcomas	Complexes with p53
Chromatin remodelers			
ALL1 (MLL)	11q23	Chromosome translocation	Chromatin modifier
Growth factors			
v-sis	22q12.3-13.1	Glioma/fibrosarcoma	B chain PDGF
Int2	11q13	Mammary carcinoma	Member of FGF family
KS3	11q13.3	Kaposi's sarcoma	Member of FGF family
HST	11q13.3	Stomach carcinoma	Member of FGF family
Growth factor receptors			
Tyrosine kinases: integral membrane protein			
EGFR	7p1.1-1.3	Squamous cell carcinoma	EFG receptor
v-fms	5q33-34	Sarcoma	CSF1 receptor
v-KIT	4q11-21	Sarcoma/GIST	Stem cell factor receptor
v-ros	6q22	Sarcoma	?
MET	7p31	MNNG-treated human osteosarcoma cell line	HGF/SF receptor
TRK	1q21-q22	Colon/thyroid carcinomas	NGF receptor
NEU	17q11.2-12	Neuroblastoma/breast	?
RET	10q11.2	Carcinomas of thyroid Men 2A Men 2B	GFNG/NTT/ART/PSP receptor activation/ fusion proteins
Receptors lacking protein kinase activity			
Mas	6q24-27	Epidermoid carcinoma	Angiotensin receptor
Signal transducers			
Cytoplasmic tyrosine kinases			
SRC	20q12-q13	Colon carcinoma	Protein tyrosine Kinase
v-yes	18q21.3	Sarcoma	Protein tyrosine Kinase

Table 3. (Continued)

Oncogene	Chromosome	Neoplasm	Mechanism of Activation
v-fgr	1p36.1-36.2	Sarcoma	Protein tyrosine Kinase
v-fes	15q25-26	Sarcoma	Protein tyrosine Kinase
ABL	9q34.1	CML	Protein tyrosine Kinase
Membrane-associated G proteins			
H-RAS	11p15.5	Colon, lung, pancreas carcinomas	GTPase
K-RAS	12p11.1-12.1	AML, thyroid carcinoma	GTPase
N-RAS	1p11-13	Carcinoma, melanoma	GTPase
BRAF	7q34	Melanoma, thyroid, colon ovary	
Gsp	20q13.3	Adenomas of thyroid	Gs alpha
Gip	17q21.3-q22	Ovary, adrenal carcinoma	Gi alpha
GTPase exchange factor (GEF)			
Dbl	Xq27	Diffuse B cell lymphoma	GEF for Rho and Cdc42Hs
Vav	19p13.2	Hematopoietic cells	GEF for Ras ?
Serine/threonine kinases: cytoplasmic			
v-mos	8q11	Sarcoma	Protein Kinase (ser/thr)
v-raf	3p25	Sarcoma	Protein Kinase (ser/thr)
Pim-1	6p21	T-cell lymphoma	Protein Kinase (ser/thr)
Cytoplasmic regulators			
v-crk	17p13.3		SH-2/SH-3 adaptor

ALL: Acute lymphoblastic leukemia; AML: acute myeloid leukemia; CML: chronic myelogenous leukemia; GTPase: guanosine triphosphatase; PDGF: Platelet-derived growth factor

Another example is the WNT glycoprotein family that inhibits the phosphorylation of β -catenin, which participate in cell-cell adhesion and activation of several signal transduction pathways [31-33]. The APC protein actively participates controlling the activity of β -catenin. In familial adenomatous polyposis, inactivating mutations of *APC* block the degradation of β -catenin by inhibiting its phosphorylation. As a result, free β -catenin in the cytoplasm translocates into the nucleus, where activates genes involved in cell proliferation and invasion [33] (Figure 1). Growth factor receptors are altered in several cancer types (figure 2) [1, 34]. In many tumors, a deletion of the ligand-binding domain of epidermal growth factor receptor (EGFR), a trans-membrane protein with tyrosine kinase activity, causes constitutive activation of the receptor in absence of ligand binding. The activated receptor phosphorylates tyrosines in the intracellular domain of the receptor, providing interactions sites for cytoplasmic proteins containing the SRC homology domain and other binding domains. These interactions deregulate signaling in several pathways. Activating mutations occur in three other members of the EGFR family (*ERBB2*, *ERBB3* and *ERBB4*) and within the kinase domains of the HER2/neu and KIT signaling receptors [35].

Such mutations occur in lung and breast cancer and gastrointestinal stromal tumors. Two classes of clinically active anti-EGFR agents have been developed: a monoclonal antibody against the extracellular domain of the receptor (e.g., cetuximab) and competitive inhibitors of the tyrosine kinase activity of the receptor (e.g., erlotinib and gefitinib) [35].

Figure 1. Dual functions of β catenina in cell adhesion and transcription activation. β catenina is in a destructive cytoplasmic complex composed of activated protein C (APC), axin, glycogen synthase kinase 3 beta (GSK-3 β), and casein kinase (CK1).

Figure 2. Examples of receptor tyrosine kinases. The epidermal growth factor (EGF), platelet-derived growth factor (PDGF) and fibroblast growth factor (FGF) receptors have been found to be involved in a variety of human cancers. Modified to [36].

Vascular endothelial growth factor (VEGF) regulates hypoxia-dependent control of gene transcription (Figure 3). The activity of VEGF is mediated by three receptor tyrosine kinases: VEGFR1 (FLT1), VEGFR2 (FLK1-KDR) and VEGFR3 (FLT4). VEGF stimulates angiogenesis in a variety of cancers, and inhibitors of VEGF and VEGFRs have been developed. Bevacizumab is a monoclonal anti-VEGF antibody, and SU5412, a small molecule, binds the receptor tyrosine kinases of the VEGFR1 and VEGFR2 as well as the kinases of the

PDGF receptor and KIT. In addition to inhibiting the ABL kinase, imatinib also inhibits the PDGF and KIT receptor kinases. Gastrointestinal stromal tumors that carry activating mutations of KIT respond to imatinib or other inhibitors of these receptor kinases [37, 38].

Figure 3. Role of VEGF-VEGFR interaction in angiogenesis. Several pathways are activated by the interaction of vascular endothelial growth factor (VEGF) and VEGF receptor (VEGFR) FAK denotes fatal adhesion kinase, Flk fetal liver kinase, IP3 inositol triphosphate, KDR kinase insert domain containing receptor, MAPK mitogen-activated protein kinase, PI3K phosphoinositol 3 kinase, PKB protein kinase B, and PLC phospholipase C. (Modified to [1].

Transcription Factors

Usually, transcription factors are members of multigene families sharing common structural domains. Many transcription factors require interaction with other proteins; for example, the Fos transcription protein dimerizes the Jun transcription factor to form the AP1 transcription factor, which increases the expression of several genes that control the cell division [39].

Chromosomal translocations often activate transcription factor genes in lymphoid cancers and sometimes in solid tumors (e. g., prostate cancer, see table 2). In certain sarcomas, chromosomal translocations resulting in fused proteins occur consistently; in Ewing's sarcoma, for example, the *EWS* gene is fused with one of a number of partner genes, resulting in aberrant transcriptional activity of the fused proteins.

The *EWS* protein is an RNA binding molecule with a domain that, when fused to a heterologous DNA binding domain, can greatly stimulate gene transcription. Prostate carcinomas carry translocations of the *TMPR552* gene that fuse with and activate *ERG1* or

ETV1. These genes are members of the Ets (E-26) family of transcription regulators, which can activate or repress genes involved in cellular proliferation, differentiation, and apoptosis.

The Ets family of transcription factors characterized by an evolutionarily-conserved DNA-binding domain regulates expression of a variety of viral and cellular genes by binding to a purine-rich GGAA/T core sequence in cooperation with other transcriptional factors and co-factors.

Most Ets family proteins are nuclear targets for activation of Ras-MAP kinase signaling pathway and some of them affect proliferation of cells by regulating the immediate early response genes and other growth-related genes. Some of them also regulate apoptosis-related genes.

Several Ets family proteins are preferentially expressed in specific cell lineages and are involved in their development and differentiation by increasing the enhancer or promoter activities of the genes encoding growth factor receptors and integrin families specific for the cell lineages. The fusion of TMPR552, which has androgen-responsive promoter elements, with an ETS related gene creates a fusion protein that increases proliferation and inhibits apoptosis of cells in the prostate gland, thereby facilitating their transformation into cancer cells [1, 40, 41].

Chromatin Remodelers

Chromatin compaction plays a critical role in the control of gene expression, replication and repair, and chromosome segregation. Two kinds of enzymes participate in the remodeling of chromatin: 1. ATP dependent enzymes that move the positions of nucleosomes, the repeating subunits of histones in chromatin around which DNA winds, and 2. Enzymes that modify the N-terminal tails of histones [42, 43].

The pattern of histone modifications constitutes an epigenetic code that determines the interaction between nucleosomes and chromatin associated proteins. These interactions, in turn, determine the structure of chromatin and its transcriptional capacity [44].

In acute lymphocytic leukemia and acute myelogenous leukemia, the *ALL1* (also named *MLL*) gene can fuse with 1 of more than 50 genes. *ALL1* is part of a very large, stable multiprotein complex. Most of the proteins in the complex are components of transcription complexes; others are involved in histone methylation and RNA processing [45].

The entire complex remodels, acetylates, and methylates nucleosomes and free histones. The fusion of *ALL1* with 1 of more than 50 proteins results in the formation of the chimeric proteins that underlie acute lymphoblastic leukemia and acute myelogenous leukemia. *ALL1* fusion proteins deregulate homeobox genes (which encode transcription factors) the *EPHA7* gene (which encodes a receptor tyrosine kinase), and microRNA genes such as *miR191* [45].

Signal Transducers

Binding of receptor tyrosine kinases to the appropriate ligand causes reorganization of the receptors and autophosphorylation of tyrosines in the intracellular portion of the molecules [46]. Autophosphorylation enhances the kinase activity of the receptor or promotes the interaction of the receptor with domains of cytoplasmic proteins that are effectors and

regulators of intracellular signaling [47]. In humans, there are approximately 120 SRC homology 2 domains in 100 different proteins that mediate responses to signals initiated by phosphorylated tyrosines. Some of these proteins share domains with enzymatic activity, whereas others link activated receptors to downstream targets. Many oncogenes encode members of signal transduction pathways. They fall into two main groups: nonreceptor protein kinases and guanosine-triphosphate-binding proteins. The nonreceptor proteins kinases are of two types: tyrosine kinases (e.g., ABL, LCK, and SRC) and serine and threonine kinases (e.g., AKT, RAF1, MOS and PIM1). Proteins involved in signal transduction become oncogenic if they bear activating mutations. An important example is PI3K and some of its downstream targets, such as AKT and SGK, which are critical in tyrosine kinase signaling and can be mutated in cancer cells [48, 49].

Apoptosis Regulators

The *BCL2* gene, which is involved in the initiation of roughly all follicular lymphomas and some diffuse large B-cell lymphomas [50, 51], encode a cytoplasmic protein that localizes in mitochondria and increases cell survival by inhibiting apoptosis. The *BCL2* family members inhibit apoptosis and are up-regulated in several other cancer types as chronic lymphocytic leukemia and lung cancer [52]. Two main pathways lead to apoptosis: the stress pathway and the death-receptor pathway (Figure 4). The stress pathway is triggered by proteins that contain the BCL2 homology 3-domain, which inactivates BCL2 and BCL-XL and inhibits apoptosis. Drugs that mimic the BCL2 homology 3-domain and can bind to BCL-XL or BCL2 (peptides or small organic molecules that bind in a groove of these proteins) are under development. The death-receptor pathway is activated by binding of Fas ligand, TRAIL, and tumor necrosis factor α , to their corresponding (death) receptors on the cell surface. Activation of death receptors activates caspases that cause cell death [53, 54] (Figure 4).

Figure 4. The two main pathways to programmed cell death, or apoptosis. The effectors of cell death are the downstream caspases, proteolytic enzymes activated by caspases 8 and 9, which are capable of clearing many of the cellular proteins causing cell death. FADD denotes Fas-associated death domain. Modified to [1].

Gene amplification usually occurs before the tumor progression; an example is the *DHFR* amplification in methotrexate-resistant acute lymphoblastic leukemia [55]. Amplification of *DHFR* is accompanied by cytogenetic abnormalities that reflect the oncogene amplification [56, 57]. The amplified DNA segment contains many genes and usually involves hundreds of kilobases. Amplification phenomenon is frequently involved in oncogenes families as *MYC*, *CCND1*, *EGFR* and *RAS*. In several cancer types as small-cell lung, breast, esophageal, cervical, ovarian and head and neck, *NMYC* amplification correlates with advanced tumor stage [58]. *CCND1* amplification occurs in breast, esophageal, hepatocellular, and head and neck cancer. *EGFR* is amplified in glioblastoma and head and neck cancer. *ERBB2* amplification in breast cancer correlates with a poor prognosis [1, 59].

Chronic Inflammation as Activation Mechanism

Inflammation is an important mechanism that can remove the agent responsible for the injury and initiate tissue repair and regeneration by a coordinated release of immune response [19]. The mechanism inflammatory involves innate and adaptive immune response. After elimination of the pathogen and wound healing, inflammation decreases [60].

However, an unsolved inflammatory process can disrupt cellular microenvironment, which leads to alterations in genes related to cancer and posttranslational modification of key proteins in the cell cycle, DNA repair and apoptosis [60].

In early stages of development and progression of tumor, mononuclear cells, macrophages, mast cells and neutrophils are present through up-regulation of pro-inflammatory cytokines such as interferon- γ , tumor necrosis factor (TNF), interleukin (IL)-1 α / β or IL-6. Also the activated nuclear factor-kB (NF-kB) is a transcription factor that relates inflammation and tumorigenesis, allowing pre-neoplastic and malignant cells evade apoptosis. Therefore, all these factors may act as initiators and promoters of carcinogenesis [60].

The role of chronic inflammation in carcinogenesis has been evaluated in several epidemiological studies, where pro-inflammatory and anti-inflammatory cytokines, viral infections and genetic markers involved in the inflammatory response were analyzed [60, 61]. It is estimated that the underlying infections and inflammatory reactions are related to 15-25% of all cancer cases [60-62].

Association between inflammatory processes and cancer are well known in the case of intestinal disease and colorectal cancer, virus hepatitis B (or C) and alcoholic liver cirrhosis or hepatocellular carcinoma, chronic esophageal reflux resulting in Barrett's esophagus and esophageal carcinoma, infection by human papilloma virus and cervical cancer, prostatitis and prostate cancer and infection by helicobacter pylori with gastric cancer [60, 63, 64]. In other cases, cancer is related with chronic irritation caused by long exposure to cigarette, silica and asbestos [63, 64].

The mechanism by which inflammation predispose cancer depends on whether it is secondary to chronic irritation or infection. In the case of HPV malignant transformation is mediated by E6 and E7 oncoproteins [65]. In other cases, the oncogenic activation occurs by the classical mode; for example, *H. pylori* contain protein factors that affect host cell signaling [66].

The chronic inflammatory response can lead to genomic injury and initiation of malignant transformation. A defense mechanism is the production of free radicals such as reactive oxygen

intermediated (ROI), hydroxyl radical ($\bullet\text{OH}$) and superoxide ($\text{O}_2\text{-}\bullet$) and reactive nitrogen intermediates (RNI), nitric oxide ($\text{NO}\bullet$) and peroxynitrite (ONOO-), which are formed by the enzymatic reaction in the host (myeloperoxidase, NADPH oxidase and nitric oxide) governed by different signaling pathways [67].

Intrinsic cellular mechanisms to prevent the unregulated proliferation or mutations in DNA are diverse, among them tumor suppressors involved in DNA repair, cell cycle arrest, apoptosis and senescence [19]. During the face of massive cell death, by infectious or noninfectious injury, cell repopulation occurs from the undifferentiated precursor cells, for which two sequential steps are required: first, some cells must survive, and second, must be a clonal expansion of this undifferentiated precursor cells in order to maintain the tissue functioning. The development of new cells is regulated by inflammatory pathways [68, 69] as part of the repair process and in defense of the infection. In initiated cells, the inflammatory response, providing cell survival and proliferation, possibly is leading to tumor promotion [19].

Evident association between tumorigenesis and host defense and / or tissue repair have been reported. Most of the studies described are based in tissue injuries and wounds that support tumor growth and neoplastic progression. For example, injection of the Rous sarcoma virus causes sarcoma in the injection site [70], probably mediated by transforming growth factor- β (TGF- β) and fibroblast growth factors (FGFs) [71]. Some metabolic signaling pathways are involved; among them the Wnt- β -catenin pathway [72] and molecules COX-1 and 2 [73].

Other studies have focused on the role NF- κB (transcription factors) in tumorigenesis. Inactivation of the classical NF- κB in colonic epithelial cells due to deletion of the I κB protein kinase β (IKK β) decreases the frequency of visible tumors [19, 74]. So in the colonic epithelium injured and that was added as a mutagen azoxymethane (AOM), the NF- κB provides a survival signal for cells initiated [75]. Otherwise, the IKK β acts protection injury infectious or non-infectious and host defense in intervening in survival of colon epithelial cells [76, 77].

Many inflammatory mediators such as cytokines, chemokines and eicosanoids stimulate the proliferation of normal and transformed cells [63]. After the administration of the phorbol ester TPA (12-O-tetradecanoylphorbol-13-acetate) and the mutagen DMBA (7, 12-dimethylbenza-anthracene) in TNF-deficient mice, fewer skin tumors were observed. Based on these experiments, the authors suggest that inflammatory mediators act as tumor promoters [78].

In the presence of tumor initiation and tissue injury and apoptosis, activation of inflammation depend tissue repair/compensatory proliferation leading to tumor promotion [19].

REPROGRAMMING OF METABOLIC PATHWAYS IN CANCER

Cancer cells require greater amounts of nutrients from the bioenergy reserves, for which different metabolic pathways are activated or modified. The signals that stimulate cell proliferation are also involved in the reorganization of the metabolic activities that allow the resting cells, initiate proliferation. The new conditions of the metabolism of cells differ from normal cells metabolism mainly by the high rate of glycolysis, lactate production, biosynthesis of lipids and other macromolecules [79].

The first observations on metabolic alterations in tumors were reported in 1920, highlighting that tumor cells of ascites in conditions of rapid proliferation consume large amount of glucose, and excrete most of the carbon as lactate, rather than oxidize it completely as do the normal cells. This phenomenon is called "Warburg effect" [80]. Warburg proposed that tumor cells use the increase of the glycolytic flow as protection before permanent damage of oxidative metabolism [79, 81]. The Warburg effect is not observed in the process of cell proliferation from all tumors [29]. This increase in the consumption of glucose, which increases the production of ATP and anabolic reactions, offers some advantages for tumor growth. *First*, for obtaining ATP, tumor cells use glucose as the most abundant extracellular nutrient in anaerobic glycolysis, and although the production of ATP per glucose is low, the high glycolytic flow generated exceeds the production of ATP from oxidative phosphorylation (OXPHOS) [29, 81]. *Second*, degradation of glucose provides the necessary intermediate compounds for different anabolic reactions, thus: ribose for synthesis of nucleotides; glucose-6-phosphate to form glycogen and ribose-5-phosphate; dihydroxyacetone phosphate for synthesis of triglycerides and phospholipids; pyruvate for synthesis of alanine and malate; and, through oxidative pentose phosphate pathway (PPP) produce nicotinamide adenine dinucleotide phosphate (NADPH) [29, 79]. *Third*, the cancer cells produce lactic and bicarbonic acid; lactate is the main end product of anaerobic glycolysis. The acidic conditions create a favorable environment for the tumor, inhibiting autoimmune effects of anti-cancer. In this atmosphere the anaerobic components (cancer cells) and aerobic (non-transformed stromal cells) are involved in metabolic pathways, complementary, recycling products of anaerobic metabolism to maintain the survival and growth of cancer cells. *Fourth*, tumors can metabolize glucose by the pentose phosphate pathway to generate NADPH and thus ensure antioxidant defenses against a hostile environment with chemotherapeutic agents [29].

In this way, the entire metabolism is reorganized to increase anabolic processes that enable growth and cell proliferation [29]. We will summarize some of the mechanisms modified in cellular signaling and key aspects of the metabolism of both normal physiological and tumorigenic proliferation. Likewise, the PI3K/Akt/mTOR pathway and the *MYC* and *HIF-1 α* transcription factors, which appear to regulate complementary aspects of cell metabolism, will be analyzed [79].

Metabolic Activity in Cell Proliferation

Normal mammalian cells do not proliferate in an autonomous way, entering the cell cycle by indication of growth factors and signaling pathways that influence gene expression and cellular physiology. The proliferating cells depend on growth factors to generate this metabolic flux and enhance the uptake of nutrients from the extracellular space [79]. In the absence of growth factors, mammalian cells quickly lose expression of transporters of nutrients and cannot keep cell autonomy for the synthesis of basal bioenergetics and macromolecular replacement. In this case, the cells carry out autophagy, which provides a limited supply of substrates generated from the macromolecular to maintain the production of ATP for cell survival [82].

The transduction of signals for cell proliferation has direct effects on the metabolic flux [79]. The mechanisms that integrate the signal transduction and cell metabolism are highly conserved between normal cells and tumor cells. The biggest difference is that in normal cells, the initiation of signaling requires extracellular stimulation, while cancer cells present

mutations chronically favoring these routes, maintaining metabolic biosynthesis phenotype, regardless of the physiological limitations of the normal cell. In other words, the cancer cells achieve an increase in metabolic autonomy. For example, in cell proliferation the enzyme lactate dehydrogenase (LDH-A) is induced by oncogenes like *HER2/neu* and *MYC* promoting cell proliferation [79]. Other enzymes highly expressed in tumors are the embryonic isoforms of pyruvate kinase (PKM2), fatty acids synthase (FASN), choline kinase (ChoK) [29, 83], and the lipogenic enzymes ATP citrate lyase and fatty acid synthase [79, 81, 84].

Rarely, tricarboxylic acid (TCA) cycle enzymes as succinate dehydrogenase (SDH) and fumarate hydratase (FH) behave as tumor suppressor; thus, mutations in the SDHB, SDHC and SDHD subunits can cause familial paraganglioma or pheochromocytoma [85], mutations in FH produce a dominant syndrome of uterine fibrosis, leiomyomata and renal carcinoma of papillary cells [79, 86]. Proliferating cells use intermediate compounds derived from the TCA cycle to synthesize lipids, proteins and nucleic acids, so use this cycle as a center of biosynthesis [79].

PI3K/Akt/mTOR Signaling Pathway

The activation of the PI3K/Akt/mTOR pathway both in growth factors dependent cells as in tumour cells, improves many of the metabolic activities that keep the cell biosynthesis by several processes. *First*, the cells increase expression of transporters and the consumption of glucose, amino acids and other nutrients [87, 88].

Second, Akt (v-akt murine thymoma viral oncogene) increases glycolysis and the production of lactate, which is sufficient to induce the Warburg effect in normal and cancer cells [89]. *Third*, PI3K and Akt stimulate the synthesis of lipids in many cell types, mTOR (mechanistic target of rapamycin) is key in regulating the protein translation [81, 90, 91].

In normal cells, the activation of the PI3K system is controlled by the phosphatase PTEN (phosphatase and tensin homolog). In malignant cells, the pathway can be triggered by mutations that activate PI3K or increase the stimuli of the system (BCR-ABL, *HER2/neu* amplification, etc.) or eliminate negative regulators of the same PTEN [79] (Table 4).

Table 4. Key mutations involved in PI3K pathway [79]

Gene	Mutation	Cancer	Frequency
PIK3CA	Gene activation	Breast	25%
		Colon	>30%
	Gene amplification	Head and neck	>35%
Akt2	Gene amplification	Ovary	12%
PTEN	Loss of heterozygosity	Glioma	≤40%
BCR-ABL	Fusion by chromosomal translocation	Chronic myelogenous leukemia	>90%
		Acute lymphocytic leukemia	20%
HER2/neu	Gene amplification	Breast	25%
EGFR	Gene amplification	Lung (non-small cell)	>50

Regulation of Glycolysis by HIF-1

One of the most important mechanisms involved in the aerobic glycolysis is the activation of hypoxia inducible factor (*HIF*); it is a transcription factor induced by hypoxic and oxidative stress, as well as oncogenic, inflammatory and metabolic factors [81, 92]. HIF-1 is a heterodimer composed of a stable β subunit and a unstable α subunit, both synthesized in normoxia by sequential action of the enzymes prolyl hydroxylase dependent of oxygen (PHDs) and ubiquitin ligase VHL [29, 81]. The active form of HIF-1 (HIF-1 α subunit) is expressed under the control of growth factor signaling pathways, mainly PI3K/Akt/mTOR [93]. In hypoxia, prolyl hydroxylation is inhibited by reactive oxygen species (ROS) from mitochondria, resulting in stable transcriptional activity of HIF-1 complex [79]. In tumor cells, stimulation by growth factors is required to express HIF-1 α , necessary for regulating the intracellular fate of carbon derived from glucose [79] (Figure 5).

Figure 5. Tumor cells near to blood vessels are well oxygenated, whereas more distant tumor cells are poorly oxygenated and express high levels of HIF-1, which induces the expression of proteins that increase: uptake of glucose (glucose transporter 1 (GLUT1); conversion of glucose to pyruvate (glycolytic enzymes [Glyc. Enz.]); generation of lactate and H^+ (LDHA); and efflux of these molecules out of the cell (carbonic anhydrase IX (CA9), sodium-hydrogen exchanger 1 (NHE1), encoding the transporter 4 monocarboxylate (MCT4). In these hypoxic cells, two moles of lactate are produced for each mole of glucose, associated with a reduced substrate delivery to the mitochondria through the action of pyruvate dehydrogenase kinase 1 (PDK1). Hypoxic cells generate 2 mol of ATP and 2 mol of lactate for each mol of glucose consumed, whereas aerobic cells generate 36 mol of ATP per 2 mol of lactate consumed. Modified to [94].

HIF-1 stimulates the conversion of glucose to pyruvate and lactate by means of glucose transporter type 1 (GLUT1), hexokinase (HK2 and HK1), LDHA and monocarboxylate transporter type 4 (MCT4). In addition, HIF-1 reduces the conversion of pyruvate to acetyl-CoA by action of the pyruvate dehydrogenase (PDH) [79, 94]. HIF-1 cooperates with the proto-oncogene *MYC* to aerobic glycolysis promotion by induction of *HK2* and pyruvate dehydrogenase kinase 1 (*PDK1*) [29, 79].

Tumor cells show cyclical changes in phases of oxygenation, which involves a dynamic regulation of metabolic symbiosis, where cells can change from a state of lactate production to one of consumption of the same. Intratumoral hypoxia is associated with increased risk of metastasis and mortality [94] (Figure 5).

Metabolic Changes and Cancer Cells

Cancer cells differ from normal cells by a number of changes in their physiological processes, including autonomous proliferation, angiogenesis, apoptosis evasion, limitless replicative potential, tissue invasion or metastasis and immune response (Figure 6) [5, 29].

- **Autonomous proliferation:** Growth factors regulate two transduction signals in the Ras/Raf/MAP kinase pathway: ERK and PI3K. Both activate mTOR to stimulate cell growth. Most cancers have mutations in the main regulators of this pathway: K-Ras, H-Ras, N-Ras, B-Raf, subunit p110a of PI3K, receptor tyrosine kinase (RTKs) or its effectors downstream (Akt and PDK1), or inactivating mutations of negative regulators of these proteins [95]. Over activation of the PI3K/Akt system in autonomous cells provides increase in the flow of glucose and amino acids that may be attributable to the activation of HIF-1a. Akt stimulates the expression of GLUT1 and translocation to the plasma membrane of GLUT4. In addition, Akt stimulates glycolysis by activation of 6-phosphofructo-2-kinase (PFK2) and synthesis of fatty acids by phosphorylation of ATP citrate lyase [29].
- **Apoptosis evasion:** Alterations in the OXPHOS can induce resistance to apoptosis. Likewise, inhibition of the respiratory chain can inhibit the activation of proteins pro-apoptotic Bcl-2, Bax and Bak [96]. In studies published by Bonnet et al. [97], the pharmacological inhibition of PDK1, an enzyme that catalyzes the phosphorylation and inactivation of PDH, produces the reactivation of PDH, induces apoptosis in cancer cells, which is an interesting example of reversal of resistance to apoptosis and metabolic reprogramming [29].
- **Continuous replication:** To immortalize the replicative power, tumor cells often mutate or inactivate inducers of senescence as the tumor suppressor p53 [98]. In glycolysis, enzyme phosphoglycerate mutase (PGM), which is negatively regulated by p53, catalyzes the conversion of 3-phosphoglycerate (3PG) to 2-phosphoglycerate (2PG) [99].
- **Angiogenesis:** In response to hypoxia and HIF-1, many tumors over-express the vascular endothelial growth factor (VEGF) by activation of the ERK and PI3K signaling pathways [29, 100]. On the other hand, mitochondrial protein F1F0-ATPase, whose function is to provide the necessary protons for aerobic glycolysis, is inhibited by angiostatin, which prevents the endogenous angiogenesis by intracellular acidification [29]. Chi et al. [101], reported an antibody similar to angiostatin with angiogenesis inhibitor effect.
- **Tissue invasion and metastasis:** E-cadherin is involved in the intercellular union [29]. Activation of HIF-1a causes loss of E-cadherin and expression of proto-oncogenes *met* and *Twist* that induce metastasis through the chemokines receptor (CXCR4) and lysyl

- Immune response: The antitumor effects of cytotoxic T lymphocytes (CTLs) can be inhibited by the metabolic micro-environment of the tumor cells [29]. The macrophages associated with tumors are markers of poor prognosis: facilitate angiogenesis as well as promotion and migration of tumor cells [104]. In advanced stage cancer, the production of lactate inhibits the production of cytokines, the CTLs cytolytic activity and the cell proliferation. Alternative therapies modifying the tumor metabolism have been proposed inhibiting the protons exportation and the production of lactate or indolamine 2, 3-dioxygenase, which could restore the defective antitumor immune response [29].

The diagram illustrates the Hallmarks of Cancer, centered around ten key features arranged in a circle:

- Autonomous proliferation**: Influenced by Akt, PI3K, mTOR, and Anabolic reactions.
- Immune response**: Influenced by Kynurenins.
- Insensitivity to antigrowth**: Influenced by Lactate, Anaerobic glycolysis, Oxygen independence, and Proton extrusion.
- Tissue invasion and metastasis**: Influenced by Extracellular acidification and HIF-1.
- Continuous replication**: Influenced by Inhibited OXPHOS, p53, PGM, Glycolysis, and F₁F₀ATPase.
- Angiogenesis**: Influenced by Ang-2, VEGF, and HIF-1.
- Apoptosis evasion**: Influenced by HK-VDAC association and Inhibited OXPHOS.

Additional pathways shown include:

- Glycolysis leading to Inhibited OXPHOS.
- Akt leading to PI3K, which leads to mTOR.
- mTOR leading to Anabolic reactions.
- Lactate being produced from Anaerobic glycolysis and influencing Proton extrusion.
- Oxygen independence leading to Anaerobic glycolysis.
- p53 leading to Inhibited OXPHOS and Glycolysis.
- HIF-1 leading to Ang-2, VEGF, and Extracellular acidification.

Figure 6. Cancer cell changes and their links to tumor metabolism. Hypothetical links between different metabolic alterations and the non-metabolic characteristics of neoplasia [circle] are depicted. Centripetal arrows indicate how the changes in cancer cells can impinge on metabolism. Centrifugal arrows illustrate how neoplasia-associated metabolic reprogramming can contribute to the acquisition of cancer changes. Ang-2: angiopoietin-2; GLUT: glucose transporter; HIF: hypoxia-inducible factor; HK: hexokinase; OXPHOS: oxidative phosphorylation; PGM: phosphoglycerate mutase; PI3K: phosphatidylinositol 3-kinase; SCO2: synthesis of cytochrome c oxidase 2; VDAC: voltage-dependent anion channel; VEGF: vascular endothelial growth factor. Modified to [29].

Table 5. Metabolic pathways in cancer as therapeutic target [29]

Target	Desired Effects	Examples of Compounds
Glycolysis		
Glucose uptake	Glucose transport or initial glycolysis inhibition.	2-Deoxyglucose has radiosensitizing and chemosensitizing effects
Hexokinase [HK1 and HK2]	Inhibition of enzymatic activity and dissociation from mitochondria	3-Bromopyruvate has potent antitumor effects in vitro and in vivo
Pyruvate dehydrogenase kinase 1 [PDK1]	Inhibition of PDK1 for deinhibition of pyruvate dehydrogenase	Dichloroacetate [DCA]
Lactate dehydrogenase A [LDHA]	Inhibition	SiRNA
Pyruvate kinase [PK] isoenzyme PKM2	Translocation of PKM2 to the nucleus for induction of apoptosis	Somatostatin and its derivative TT-232 [in vitro]
Fatty Acid Synthesis		
ATP citrate lyase [ACL]	Inhibition	SB-2049990 inhibits pancreatic cancer growth in nude mice
Acetyl-CoA Carboxylase [ACC]	Inhibition	Sorafenib A induces apoptosis or autophagy in vitro
Fatty acid Synthase [FASN]	Inhibition	Cerulenin and its derivative C57 inhibit human ovarian cancer
Choline kinase [ChoK]	Inhibition	MN58b reduces phosphomonoesters in human cancer xenografts
HIF		
HIF-1 α prolylhydroxylases [PHDs]	Activation of PHDs for inhibition of HIF	Cell-permeating α -ketoglutarate derivatives reverse HIF activation in SDH- or FH-deficient cells
Hypoxia-inducible factor 1 [HIF-1]	Inhibition of DNA binding	Echinomycin
Reactive oxygen species [ROS]	Antioxidants neutralize ROS and reduce HIF-1 function via PDHs and VHL	N-acetylcysteine [NAC]; vitamin C
Hypoxia	Cytotoxic effects of components enriched in hypoxic cells	Tirapazamine [TPZ], a hypoxia activated prodrug.
Proton Extrusion		
Na ⁺ /H ⁺ exchanger	Inhibition	Cariporide
Bicarbonate/Cl ⁻ exchanger	Inhibition	S3705
MCT1 lactate /H ⁺ symporter	Inhibition	α -cyano-4-OH-cinnamate
Carbonic anhydrases 9 and 12 [CA9 - CA12]	Inhibition	Sulfonamide indisulam
F ₁ F ₀ ATP synthase	Inhibition	Angiostatin; antibodies
Other		
AMPK	Activation	Biguanides and thiazolidinediones activate AMPK through inhibition of OXPHOS, reducing the risk of cancer in diabetic patients
eIF4E	Inhibition of translation initiation by eIF4E	Antisense oligonucleotide inhibits growth of human breast cancer
L-type amino acid transporter 1 [LAT1]	Inhibition to reduce amino acid transport	2-aminobicyclo [2.2.1]-heptane 2-carboxylic acid inhibits tumor growth in a xenograft model

CANCER INITIATION AND PROGRESSION

Cancer is a very heterogeneous disease. Tumors that arise in the same tissue can even exhibit an array of cellular pathologies, ranging from benign hyperplasia to highly invasive malignancies. On the other hand, cancer is a complex disease which involves the deregulation of multiple pathways. Microarray analysis has identified thousands of genes that are transcriptionally deregulated in cancer [107]; however, it remains unclear which deregulated genes play a causative role in tumor initiation and maintenance and which ones represent passerby with no selective advantage. Regardless of the role that specific genes may play in cancer progression, when a tumor is histological or clinically identified, a large number of molecular lesions have been accumulated [108].

A literature survey on all published cancer genes identified 291 genes for which there were molecularly characterized mutations and evidence of a causative role in tumorigenesis; these genes represent more than 1 percent of the human genome [109]. The large number of mutations found in tumor samples raises the question of whether there exists a common thread that underlies most, if not all, human malignancies, or biological rules that govern cancer initiation and progression. Despite the heterogeneity observed in cancer, most tumors share certain characteristics: self-sufficiency in growth signals, insensitivity to anti-growth signals, evasion of apoptosis, acquisition of a limitless replicative potential, sustained angiogenesis, and tissue invasion and metastasis [5, 108]. The similarity in the cellular processes in all cancer cells, regardless of their tissue of origin, likely indicates common tumor-initiation mechanisms.

When chronic myelogenous leukemia converts to acute leukemia, the malignant clone acquires an additional t(9;22) translocation, an isochromosome 17, or trisomy of chromosome 8. Likewise, when follicular lymphoma becomes aggressive, the lymphoma cells often bear a t(8;14) translocation in addition to the original t(14;18) translocation [1]. These findings support the hypothesis that most hematopoietic tumors and soft-tissue sarcomas are initiated by the activation of an oncogene, followed by alterations in tumor-suppressor genes and other oncogenes. In contrast, most carcinomas are initiated by the loss of function of a tumor-suppressor gene, followed by alterations in oncogenes and additional tumor-suppressor genes [110].

Comparative genomic hybridization has revealed a number of genes that can be amplified or deleted in cancer. Breast cancer genome analyses indicate that there are only a few genes that are frequently mutated but many that are rarely mutated, providing an explanation for the heterogeneity in cancer. Complex somatic DNA rearrangements, mostly intra-chromosomal duplications, have been found in the breast cancer genomes [111].

Genome sequences of primary breast cancer and cancer metastasis show restricted de novo mutations in metastasis, but significantly shared mutations in the primary tumor. These studies provide information on tumor evolution and identify pathways critical to breast cancer metastasis [112].

The *ErbB2*, *PI3KCA*, *MYC*, and *CCND1* oncogenes are frequently deregulated in breast cancer. Loss-of-function mutations of *RB* in breast cancer cell lines and primary tumors were reported since 1988 [113]. At least ten tumor suppressor genes, all of which are involved in the regulation of genomic integrity, have been associated with hereditary breast cancer [114].

Cellular transformation is thought to take place through the accumulation of mutations, as well as epigenetic changes, that activate oncogenes or down regulate tumor-suppressor genes

and lead to uncontrolled clonal expansion. Oncogenes originally were identified as the transforming agents of tumor viruses; later oncogenes were recognized as mutated versions of normal cellular genes, or proto-oncogenes, which had been incorporated into the viral genome by recombination [115].

The positive control of cellular growth is associated with mutations in oncogenes, which are generally dominant. In contrast, tumor suppressor genes function as negative regulators of cellular growth and are generally recessive. Thus, inactivation of both copies of a tumor-suppressor gene is usually necessary for tumor development. Several lines of evidence indicate that mutations in a single oncogene or tumor suppressor are insufficient to give rise to cancer [115]. First, most cancers develop late in life and the incidence of disease increases dramatically with age. Statistical analysis of epidemiological data shows that a cell needs to accumulate four to five sequential genetic lesions in key regulatory pathways in order to become malignant [116]. Second, *in vitro* experiments using cell lines, as well as *in vivo* models of cancer, confirm the multiple-hit hypothesis (retinoblastoma and certain types of leukemia are exceptions). Experiments using retroviruses containing activated versions of growth-controlling genes could lead to transformation of rodent cells in culture [117, 118]. However, the cells used in these initial cancer studies were immortal and could therefore proliferate indefinitely. When these experiments were repeated with primary cell lines, it was found that activation of at least one pair of oncogenes was required for transformation [119].

Tumors are histologically classified as presenting with different “grades,” which correspond to a set of physiological markers as loss of differentiation, abnormal ploidy, and morphology, and correlate with patient outcome. Higher grade tumors have a more negative prognosis, while low-grade tumors are often considered early lesions and may progress to more invasive, high-grade disease. These observations have led to the hypothesis that cancer progression can be dissected into a small number of crucial steps whose sequential deregulation is critical for the clinical progression from low- to high-grade cancer. At least four pathways must be altered in order for tumor progression to occur: maintenance of telomere length (achieved by expressing human telomerase), deregulated cell-cycle entry (inactivation of *Rb*), deregulated cell growth arrest and apoptosis (inactivation of *p53*), and growth-factor independence (by oncogenic *Ras* overexpression). It remains to be explored how different oncogenes and tumor-suppressors found in tumor samples contribute to these cancer pathways and how they interact with each other to reinforce their tumorigenic potential [120].

Multistep process observed in human cancer has also been found in mouse models carrying activated oncogenes or inactivated tumor-suppressor genes, in which the duration and aggressiveness of the disease can be changed by introducing into the mouse genome the same sequential genetic alterations observed in human tumors.

ONCOGENES AS THERAPEUTIC TARGETS

Cancer mouse models have been used to test the hypothesis that, if tumor growth remains dependent on their original transforming oncogenic mutations, oncogene inactivation could lead to tumor regression [121]. Several studies evaluating the over expression of the *MYC* oncogene in lymphoid and epidermal tissues showed that the inactivation of *MYC* led to sustained tumor regression with concomitant promotion of either differentiation or apoptosis

[121-123]. However, in other models, a fraction of tumor cells were refractory to *MYC* inactivation; these cells presumably had acquired new mutations that allowed Myc-independent growth [124-126].

The main cause of treatment failure for cancer patients are the metastasis. According to the model of metastatic progression only a small subset of cells from the primary tumor acquire the requisite mutations to metastasize to distant sites, where new mutations are accumulated as a response to the different selective pressures of a novel environment [127]. However, recent data suggest that most cells in primary tumors with metastatic potential already contain the lesions necessary for metastasis and, possibly, for survival in a foreign environment. Microarray analysis compared patterns of gene expression in breast cancer patients with their known five-year survival and recurrence rates. Seventy genes were identified that could predict clinical outcome with a combined 83 percent accuracy [128]. Moreover, solid tumors of different origin shared the same metastatic signature, implying there is a common set of molecules regulating metastasis in a variety of primary tumors [129, 130].

Oncogenic proteins in cancer cells can be targeted by monoclonal antibodies when expressed on the cell surface, or by small molecules acting on specific molecules in particular metabolic ways. For example, imatinib targets the initial step of the multistep process in chronic myelogenous leukemia [131]. The same drug can affect the KIT and PDGFR receptor kinases. [132, 133]. Of particular interest are inhibitors of the BCL2 family, which can induce the apoptotic death of cancer cells. In acute promyelocytic leukemia, which is initiated by a t(15;17) chromosome translocation that fuses the *PML* gene to *RAR α* (a nuclear receptor for retinoic acid), addition of retinoic acid can induce terminal differentiation and death of APL cells. This modality is called differentiation therapy [134, 135].

MicroRNA Genes

Recent findings in molecular biology show that the participation of small regulatory non-coding RNA is required for cellular diversity in developing and mature organisms. These molecules act as sequence-specific post-transcriptional regulators in the expression of other RNA transcripts [136]. Small regulatory non-coding RNA molecules include microRNAs (miRNAs), small interfering RNAs (siRNAs) and repeat-associated siRNAs (rasiRNAs), which are unified by their association with the argonaute (AGO) family of proteins and by their function. All these RNAs direct the binding of protein complexes to specific nucleic acid sequences [137- 139].

Unlike other genes involved in cancer, miRNAs do not encode proteins. Their products are a single RNA strand of about 21 to 23 nucleotides implicated in to regulate the gene expression. A miRNA molecule can anneal to a messenger RNA (mRNA) containing a complementary nucleotide sequence and blocking the protein translation or causing degradation of the mRNA [140]. Mapping of numerous miRNA genes has shown that many of them occur in chromosomal regions that undergo rearrangements, deletions, and amplifications in cancer cells. The genome regions that are consistently involved in chromosomal rearrangements in cancer cells but that lack oncogenes or tumor-suppressor genes appear to harbor miRNA genes [141].

Recent studies have shown that the RNA Pol III drives miRNA transcription from dense human clusters interspersed among repetitive Alu elements. These gene clusters are transcribed

as polycistronic primary transcripts and subsequently cleaved into multiple miRNAs, or from intergenic regions as independent transcriptional units, or from intronic sequences of protein-coding or non-coding transcription units or exonic sequences of non-coding genes [142] (Figure 7).

Primary miRNAs transiently receive a 7-methylguanosine (7mGpppG) cap and a poly(A) tail and is processed into a precursor miRNA (pre-miRNA) by the nuclear RNase III enzyme Drosha and its partner DiGeorge syndrome critical region gene 8 (DGCR8). Exportin-5 transports pre-miRNA into the cytosol, where it is processed by the Dicer RNaseIII enzyme into a mature double strand miRNAs. The RNA strand is recruited into the RNA-induced silencing (RISC) effector complex and assembled through processes that are dependent on Dicer and other double strand RNA binding domain proteins, as well as on members of the argonaute family. MiRNAs guide the RISC complex to the 3' untranslated regions (3'-UTR) of the complementary messenger RNA (mRNA) targets for repress their expression by several mechanisms: repression of mRNA translation, destabilization of mRNA transcripts through cleavage, deadenylation, and localization in the processing body (P-body), where the miRNA-targeted mRNA can be sequestered from the translational machinery and degraded or stored for subsequent use. Nuclear localization of mature miRNAs has been described as a novel mechanism of action for miRNAs. Scissors indicate the cleavage on pri-miRNA or mRNA [143].

Expression profiling of miRNA genes has revealed signatures associated with tumor classification, diagnosis, staging, and progression, as well as prognosis and response to treatment. For example, miRNA expression profiling can distinguish between indolent and aggressive forms of chronic lymphocytic leukemia, and expression of a small panel of miRNA genes correlates with prognosis in lung cancer [144- 146].

Some miRNA genes that are deregulated in chronic lymphocytic leukemia have germ-line or somatic mutations in a miRNA precursor that affect the processing of short single-stranded miRNA molecules [144]. MiRNA genes can be up-regulated or down-regulated in cancer cells. The up-regulated miRNA genes function as oncogenes by down-regulating tumor-suppressor genes, whereas the down-regulated miRNA genes function as tumor-suppressor genes by down-regulating oncogenes [147]. Table 6 display a number of examples of up or down regulated miRNAs in cancer.

The function of miRNA genes depends on their targets in a specific tissue. A miRNA gene can be a tumor suppressor if its critical target is an oncogene and it can be an oncogene if its target is a tumor-suppressor gene. Up-regulation of miRNA genes can be due to amplification, deregulation of a transcription factor, or demethylation of CpG islands in the promoter regions of the gene. For example, the ALL1 (MLL) fusion proteins of acute lymphoblastic leukemia or acute myeloblastic leukemia carrying chromosome 11q23 translocations target the Drosha nuclease complex to specific miRNA genes, including *miR191*, thereby enhancing the processing of their miRNA precursors [148]. The *miR191* gene is also up-regulated in numerous types of solid cancers [149], suggesting that it is the downstream target of signal-translocation pathways involved in cancer. MiRNA genes functioning as tumor suppressors can be down-regulated because of deletions, epigenetic silencing, or loss of the expression of one or more transcription factors [150].

The *miR155* gene is over expressed in diffuse large B-cell lymphoma, the aggressive form of chronic lymphocytic leukemia, and in breast, lung, and colon cancers [151]. In transgenic mice under control of the E μ enhancer of the immunoglobulin genes, over expression of

miR155 causes acute lymphoblastic leukemia or high-grade lymphoma, indicating that deregulation of a single miRNA gene can cause malignant transformation. Since it takes several months for the tumors in these mice to become aggressive, it is likely that additional genetic alterations are needed for the development of truthful neoplasia [152].

The *LET7* miRNA family, which are deleted or under expressed in lung cancer, target *RAS*; loss of *LET7* results in overexpression of *RAS* [153]. *MIR15a* and *miR-16-1*, the microRNAs those are deleted or down-regulated in chronic lymphocytic leukemia, cause overexpression of *BCL2*, which protects cells from apoptosis [154].

The expression of a set of 21 miRNAs is altered in at least three types of solid tumors [149]. Among these, *miR21* is of particular interest because inhibits expression of the tumor suppressor PTEN, which encodes a phosphatase involved in the PI3K kinase signaling pathway and is mutated in advanced breast, lung, gastric, and prostate cancers [155].

Table 6. MiRNAs aberrantly expressed in cancers [146]

Cancer type	Up regulated	Down regulated
Breast cancer	miR-10b, miR-21, miR-22, miR-27a, miR-155, miR-210, miR-221, miR-222, miR-328, miR-373, miR-520c	let-7, miR-7, miR-9-1, miR-17/miR-20, miR-31, miR-125a, miR-125b, miR-146, miR-200 family, miR-205, miR-206, miR-335
Chronic lymphocytic leukemia	miR-21, miR-155	miR-15, miR-16, miR-29b, miR-29c, miR-34a, miR-143, miR-145, miR-181b, miR-223
Lung cancer	miR-17-92 cluster, miR-21, miR-106a, miR-155	miR-1, let-7 family, miR-7, miR-15a/miR-16, miR-29 family
Lymphoma	miR-17-92 cluster, miR-155	miR-143, miR-145
Prostate cancer	miR-221, miR-222	miR-15a-miR-16-1 cluster, miR-101, miR-127, miR-449 ^a
Glioblastoma	miR-21, miR-221, miR-222	miR-7
Hepatocellular carcinoma	miR-17-92 cluster, miR-21, miR-143, miR-224	miR-1, miR-101, miR-122a
Colorectal cancer	miR-17-92 cluster, miR-21	miR-34a, miR-34b/c, miR-127, miR-143, miR-145, miR-342
Gastric cancer	miR-21, miR-27 ^a	miR-143, miR-145
Ovarian cancer	miR-214	miR-34b/c, miR-200 family
Melanoma	miR-221, miR-222	let-7 ^a , miR-34 ^a
Head and neck squamous cell carcinoma	miR-21	let-7d, miR-138, miR-205

Primary miRNAs (pri-miRNAs) receive a 7-methylguanosine (7mGpppG) cap and a poly(A) tail. The pri-miRNA is processed into a precursor miRNA (pre-miRNA) and exported by the protein exportin-5 into cytosol, where is processed by the Dicer RNaseIII enzyme, into 22 nt-long double strand miRNAs. Then, miRNAs guide the RISC complex to the untranslated regions of the mRNA targets for repressing their expression.

Figure 7. On the top line: (A) Gene clusters giving polycistronic primary transcripts and cleaved into multiple miRNAs; (B) intergenic regions transcribed as independent transcriptional units; (C) intronic sequences (in grey) of non-coding transcription units or exonic sequences (black cylinders) of non-coding genes. TF: transcription factor.

Chapter 103

**DICER AND MICRORNAS:
ONCOMIRS ARE THE NEXT FRONTIER
OF ONCOGENES AFFECTING CANCER
ETIOLOGY AND TUMOR PROGRESSION**

ABSTRACT

Recent understanding of oncogene regulation has uncovered an emerging new field of molecular cancer biology in which tumor suppressors and mediators are controlled through RNA regulation. Among the most critical players are microRNA (miRNA), also referred to as 'oncomirs', and Dicer, the major enzyme responsible for cleaving double-stranded RNA and forming the RNA induced silencing complex. These components are aberrantly expressed in cancer and among some tumor types are hypothesized to be causative to the etiology of malignancy. For example, prostate and colorectal cancers express abundantly high levels of Dicer mRNA while lung, ovarian and endometrial cancers express low levels of Dicer, which is believed to correlate to poor cancer prognosis. In addition, mutations of the Dicer encoding gene (*DICER1*) occur in non-epithelial ovarian cancers and pediatric tumor pleuropulmonary blastoma. Paradoxically, Dicer is a haploinsufficient tumor suppressor; the loss of a single allele of *DICER* enhances tumor growth where the loss of the second allele results in halting tumor proliferation. MicroRNA regulates oncogenic signaling pathways as well as the expression of tumor suppressors and oncogenes, making it a major contributor to the overall status of the cell and its malignant potential. The let-7 miRNA family members are well-known as tumor suppressor genes, which target and silence the Ras oncogene. On the other hand, miRNAs may induce tumor growth; one example is miR-17-19 cluster negatively regulating two tumor suppressor genes, PTEN and Bim. In this chapter, the regulation of oncomirs will be discussed with focus on the

post-transcriptional control by miRNA biogenesis machinery, which consist Dicer as a major player.

INTRODUCTION

MicroRNAs (miRNAs) are noncoding RNAs 18-25 nucleotides in length, which regulate gene expression by targeting messenger RNAs (mRNAs). Through miRNA binding to mRNA's complementary base pair sequences, mRNA is then degraded, which ultimately silences gene expression in the cell. Alternatively, gene silencing may also be achieved by translation inhibition without a requirement for exact complementarity. Profiling miRNAs in human cancer showed that miRNA expression differs between normal and cancer tissues, and also between tumor types [1]. MicroRNAs are suggested to have roles in cancer development both as oncogenes as well as tumor suppressors [2, 3]; therefore they are referred as 'oncomirs'. To further complicate the issue, other miRNAs like miR-146 and miR-29 are context-dependent [4], which means they can function as either an oncogene or tumor suppressor, depending on the cell type and the specific regulatory pathways that are either functional or deficient in that system.

MICRORNA AND CANCER

MicroRNAs regulate mRNA levels by directing the RISC to the 3'-untranslated region (UTR) of target mRNAs by complementary sequences on miRNAs to achieve gene silencing [5, 6]. The RISC complex contains Ago, an RNase III endonuclease. Although human cells have four Ago proteins (Ago1-4), only Ago2 in the miRNA-RISC complex processes mRNA cleavage [7]. The extent of complementarity between miRNAs and target mRNAs also determines whether the mRNA will be cleaved or just inhibited from translation [6]. A single miRNA can regulate different target genes and one target mRNA can also be regulated by multiple miRNAs [3].

Since miRNAs regulate multiple fundamental biological processes, alterations in their normal functioning could result in contributing to the etiology of cancer. As such, research continues to elucidate the roles of miRNAs in tumorigenesis as both tumor suppressors and oncogenes. Analysis of tumor and normal tissues from different types of cancers showed altered expression levels of many miRNAs, either via overexpression or downregulation [1, 8-15]. To date many miRNAs have been identified for their crucial roles in cancer, among them the let-7 family and the miR-17-92 cluster are well studied as tumor suppressors and oncogenes.

MICRORNA-BASED THERAPIES IN CANCER

Increasing evidence demonstrates significant regulatory roles of miRNAs. Due to their aberrant expression and function in cancer, miRNAs and their antagomirs have become appealing therapeutic potentials against cancer. There are three principal directions or applications for miRNA therapies. The first application for miRNAs as therapeutics consists of

replacing the lost miRNA or using antagomirs as direct targets against malignancy, which means overexpressing antitumor miRNAs and/or repressing oncogenes. Combinations of appropriate miRNAs or antagomirs might increase specificity to the target and reduce the risk for acquired resistance. In order for this approach to be successful at the level of molecular mechanisms, an in-depth knowledge of all the biological targets and regulatory pathways, including the ensuing off-target effects would have to be elucidated for a given miRNA first.

The goal of the second application is to increase drug sensitization of cancer cells through modulation of related miRNAs. This direction is based on the results from multiple labs, which show that despite some miRNAs not displaying significant direct effects on cancer cell survival, their alterations increase cancer cell sensitivity to drug treatment or radio therapy [16-18]. With this approach, a new era in pharmacogenomics would emerge since it is highly likely there would be significant patient variability to drug resistance and miRNA expression. The third application of miRNA therapies is inhibiting specific aberrant functions of cancer cells in a context-dependent fashion (e.g., cancer invasion and migration) through the modulation of specific miRNAs, such as miR-34a, miR-34b, and miR-21 [19-21]. To sum up, miRNA therapies are attempts to block “bad miRNAs” and increase “good miRNAs” to achieve the desired therapeutic effects.

Since foreign oligonucleotides like synthetic small-interfering RNA (siRNA) molecules in general are subject to degradation by nucleases, many modifications have been developed to increase their stability. At the same time, increases in potency and reductions in toxicity have been improved from early modifications such as phosphorothioate antisense oligonucleotides, 2'-O-methyl or 2'-O-methoxy-ethyl anti-sense oligonucleotides [22-26]. Synthetic anti-sense oligonucleotides, which have complementary sequences to oncogenic miRNAs, are used to inactivate miRNAs at tumor sites. An improvement to these is the cholesterol conjugation of anti-sense oligonucleotides, which are very stable in vivo and improves therapeutic efficacy [27-29].

Among all the chemical modifications of antisense oligonucleotides, LNA is likely the most common. For example, it is used to create antagomirs for miR-34a and the miR-17-92 cluster in vivo and in vitro [30-33]. Locked nucleic acid (LNA) is defined as an oligonucleotide that contains one or more 2'-O,4'-methylene- β -D-ribofuranosyl monomer(s) [30]. Furthermore, LNA mediated silencing of miRNA-122 has reached clinical trials in non-human primates [34-36]. It will be intriguing to follow this progress and learn whether or not these modifications are sufficient for the application of miRNA therapy.

Since miRNAs are highly tissue specific, another challenge is to deploy these therapeutics at the appropriate site. In this regards, multiple efforts have been spent on developing carriers to deliver antitumor miRNAs to tumors and even a greater understanding of how miRNAs are transported in biological systems. Interestingly, studies have demonstrated that miRNAs are highly stable and abundant extracellular entities found in circulating plasma and protected from degradation by endogenous RNases, although subject to degradation by proteases [37, 38]. Thus, circulating miRNAs are protected through several mechanisms, including binding and forming a complex with Argonaute2 [38], secretion into microvesicles from the cell and high-density lipoproteins [39].

The scenario of the normal regulation of miRNAs in circulation may differ from lessons learned through the usage of foreign siRNAs, which have several challenges during the process to reach targets. First, foreign siRNAs are degraded in plasma by nucleases [40] (whereas endogenous miRNAs have natural protection). Second, siRNAs are cleared from circulation

rapidly through kidney filtration due to their small size [41]. Third, oligonucleotides' negative charge prevents them from passing through the cellular lipid bilayer, which is impermeable to ions and polar molecules. Fourth, even after cellular internalization, foreign oligonucleotides still need to escape endosomal entrapment and degradation in order to get loaded by the RISC complex and target complementary mRNAs.

To overcome barriers and facilitate therapeutic usage of miRNAs, several delivery systems have been introduced. Viral vector-based systems were successfully tested in murine models of lung and liver cancer [42, 43]. However, because safety and host immune responses are considerable concerns for viral vectors, lipid based delivery systems are a more promising option for clinical use. Using a liposome, which is a lipid bilayer vesicle, has been developed to carry nucleic acids for an unusually long time. The lipid cage allows the liposome to remain in circulation for a much longer time [44]. The particle itself is biodegradable to optimize safety administration to host body [41]. Moreover, the liposome lipid membrane can be cationized to improve cellular fusion and uptake [45]. Antibody incorporation into the liposomal membrane increases target site specificity, thus reducing undesirable off-target effects [46, 47]. Further techniques help facilitate liposomes to escape from endosomal engulfment, such as ion-pair formation, the "proton sponge" effect or de-assembly [41].

Other methods and rising trends in cancer therapy include using nanoparticles, either lipid-based or nonlipid-based, to deliver miRNAs or antagomir oligonucleotides. Interfering nanoparticles (iNOPs), a lipid nanoparticle with its surface modified with cationic lysines, has succeeded in delivering anti-miR-122 to mouse liver [48, 49]. Nanoparticles coated with cell-penetrating peptides were used to increase the efficiency of anti-miRNA-155 delivery to cancer cells [50]. Gold nanoparticles are another promising delivery system due to reduced toxicity, a favorable ability to penetrate cells, a longer retention in circulation and easiness in biosensing [51-55]. Gold nanoparticles conjugated with miRs or antagomirs have good transfection and delivery results in vitro [56-58].

MICRORNA BIOGENESIS AND DEGRADATION

MicroRNAs are transcribed by RNA polymerase II into large RNA precursor primary-miRNA (pri-miRNA) [59, 60]. Similar to mRNAs, pri-miRNAs have caps at the 5' end and are poly-adenylated at the 3' end [61]. Pri-miRNAs form stem-loop secondary structures and are processed in the nucleus by Drosha and DGCR8, reducing the structure from hundreds of nucleotides to approximately 70-nucleotide pre-miRNAs [62]. Pre-miRNAs are then exported to the cytoplasm by Exportin-5 (Exp-5) [63]. In the cytoplasm, pre-miRNAs are cleaved by DICER, with assistance from TARBP2, to generate a 22-nucleotide, double-stranded miRNA-miRNA* duplex, which is also referred to as the miR-5p/miR-3p duplex [64, 65]. Mature miRNAs and miRNAs* are then separated and miRNAs are loaded into the RNA-induced silencing complex (RISC) while miRNAs* are more often degraded [66, 67].

However, recent publications, including our own, have altered our understanding of the fate of miRNAs* and questioned whether they are always degraded. More work is needed to elucidate the roles and contributions of these so-called "passenger" strands because studies have shown significant effects of miRNAs* in cancer and also suggested they have important regulatory abilities on their own [68-70]. It is no longer the accepted dogma that miRNAs* are

simply non-functional byproducts of the miRNA-miRNA* duplex and have no purpose other than degradation. This is an exciting time in the field of miRNA research because there is still much to uncover in our understanding of these strands and which biological effects they regulate. In particular, are they involved when things go awry and lead to cancer?

LET-7 FAMILY

Let-7 in Cell Differentiation

Let-7, together with lin-4, was the first known miRNA [71-73]. Let-7 was first identified in the nematode *Caenorhabditis elegans* as a component involved in early development [71]. In *C. elegans*, let-7 is important for and highly expressed during the larval-to-adult transition. In this period, a type of *C. elegans* stem cell called seam cells switches from proliferating in the early larval stage to terminal differentiating [71]. In the absence of functioning let-7, seam cells fail to exit the cell cycle at this transition point, thus continuing to divide instead of differentiating. As a result, the let-7 mutant animals die by bursting through vulvas, and that is the origin of the name let-7, which means lethal-7 [71]. The sequence of let-7 and its temporal expression are conserved in a wide range of animal species, from as simple as *C. elegans* to as complicated as humans [74]. In zebra fish let-7 is also detected at 48 hours after fertilization, in annelids and mollusks, the time points are adult stages [74]. Later sequencing in mouse and humans extends let-7 to a family of identical mature miRNAs encoded by 13 genomic loci from let-7a to let-7i [75]. Among them, let-7a has its sequence identical across species; while the other members keep the seed sequence but vary in other nucleotides. Current hybridization-based techniques, such as microarray and northern blot, can hardly distinguish closely related miRNAs. Thus, it is a challenge to quantify each single let-7 family member in one sample. For this reason, in this book chapter we will refer to let-7 as a term to generally describe this whole let-7 family. Let-7 is reportedly absent in embryonic stem cells or pluripotent cells but up-regulated in differentiating cells, such as brain cells, or breast stem-cell progenitors at the differentiating phase [76-80]. Lower expression of let-7 is observed as one feature of certain types of stem cells while overexpression of let-7 seems to reduce dividing [80]. Let-7 is considered one factor involved in switching cells from the proliferation phase to differentiation phase [81].

LET-7 AND CANCER: RAS, HMGA2 AND THE CELL CYCLE

The early evidence of let-7's role in cancer was the observation that let-7 expression levels are reduced in lung cancer tissues and this event is associated with shorter postoperative survival among patients [90]. Furthermore, let-7 miRNAs are mapped to the frequently deleted chromosomal sites in lung cancer [91]. More importantly, the introduction of let-7 to a low-let-7 lung cancer cell line inhibited cell growth [90].

Based on this information, a later study showed that down regulating Ras is one important mechanism whereby let-7 ceases lung cancer cell growth [92]. Ras is an enzymatic protein at the cell membrane, which is activated through binding to GTP and then triggering a cascade of

downstream signaling events, including ERK/MAPK activation [82]. Ras signaling cascades favor cell proliferation and survival [83, 84]. Mutations in *RAS* genes (e.g., *HRAS*, *NRAS* and *KRAS*), which cause increased Ras expression and activity, are reported in a number of different cancers, including pancreatic and colorectal [85-87]. Similarly, overexpression and increased activity of Ras due to *RAS* gene mutations occurs in lung cancer [88, 89]. There are multiple let-7 complementary sites in the 3' UTRs of human *RAS* genes, allowing let-7 to bind and block the expression of Ras through Ras mRNA silencing [92]. The antitumor effect of let-7 was proved in vivo when the delivery of let-7 reduced tumor burden in K-Ras G12D, a Ras mutated, human lung cancer xenograft model [93]. Beside Ras, HMGA2 is another oncoprotein regulated by let-7 [94]. HMGA2 is a member of the high mobility group AT-hook (HMGA) family, a family of nonhistone chromatin proteins that act as architectural transcription factors [95]. HMGA2 is involved in the transcription of various genes and is essential for growth during embryonic development [95-97]. HMGA2 is reported to be up-regulated in tumors, such as lung cancers and liposarcomas [97-99]. Taken together, HMGA2 is suggested to be an oncogenic factor in differentiated tissues, which express negligible HMGA2 under normal conditions. Multiple studies have provided evidence of let-7 as a negative regulator of HMGA2 in cancers [94, 100, 101]. Sequencing and reporter assays confirm that the 3'UTR of HMGA2 contains let-7 complementary sites [94, 100]. In fact, removing the let-7 complementary sites in HMGA2 3'UTR causes HMGA2 overexpression and tumorigenesis [100]. Interestingly, a study on self-renewing-tumor-initiating breast cancer cells showed that increased let-7 levels had negative effects on both Ras and HMGA2, while Ras seemed to be involved in self renewal and HMGA2 was involved in differentiation [102]. However, the antitumor effects of let-7 though Ras and HMGA2 are not always equal. In non-small cell lung cancer, overexpression of let-7 caused a reduction in both Ras and HMGA2, but ectopic expression of Ras showed a reversal of effects to let-7 mediated tumor suppression more so than ectopic expression of HMGA2 [42]. It is predicted that one miRNA strand can target hundreds of mRNAs. Correspondingly, let-7 exerts antitumor effects through not only Ras and HMGA2 but also many other targets that are important to the regulation of the cell. For example, a large number of cell-cycle genes have been identified to have let-7 complementary sites [103]. Among them, *CDC25A*, which is an oncogene, *CDK6* and *cyclin D1* are confirmed to be directly regulated by let-7 [103-106]. Upsetting the delicate balance of the regulation of the cell cycle could wreck havoc upon normal cells and homeostasis. In some systems these alterations are involved in the etiology of cancer.

REGULATION OF LET-7

Lin-28 inhibits the processing of let-7 family members through binding to pri-let-7, then blocks the let-7 precursor from Drosha-DGCR8 cleavage in the nucleus [107, 108]. This binding and blocking process is mediated through the recognition of Lin-28 to several conserved nucleotides shared by let-7 family members, thus it seems to be selective for the let-7 family with little or no effect observed on other miRNAs [107-110]. Another step that Lin-28 uses to negatively regulate let-7 is inducing the uridylation and recruiting the uridylating enzyme TUT4 to pre-let-7 in the cytoplasm [111-114]. All these modifications block pre-let-7 from being processed by Dicer to form mature let-7 and ultimately cause it to be degraded in

the cytosol [113]. Lin-28 facilitates cellular transformation and is overexpressed in multiple human primary tumor types in concert with let-7 reduction [115]. Lin-28 is believed to be involved in let-7 regulation from the observation that Lin-28 expression is high in early developmental stages and low during differentiation, which is reciprocal to let-7 levels [116]. The same reciprocal pattern is also observed in cancer cells [117, 118]. Furthermore, Lin-28 is identified as one of the four genes that together can convert human adult fibroblasts to pluripotent stem cells (the others three names are Oct4, Nanog and Sox-2) [119]. Even though it is regulated by Lin-28, let-7 creates a regulatory loop through direct targeting of Lin-28 mRNA 3'UTR [120, 121]. These pieces of evidence suggest that let-7 can escape Lin-28 mediated down-regulation and amplify itself [121, 122].

In the process of transforming from somatic cells to pluripotent stem cells, Lin28 can be replaced by Myc [123, 124]. Myc is an oncogenic transcription factor, which induces tumorigenesis through transactivating multiple genes involved in proliferation and survival [125-128]. Interestingly, very similar to Lin-28, Myc also inhibits let-7 expression through binding to promoters or sequences upstream of genes encoding the let-7 family and directly repressing transcription [129]. On the other hand, Myc induces Lin-28B expression, which in turn further represses let-7 maturation as described above [130]. Again, similar to the case of Lin28, let-7 comes back to directly target and down-regulate Myc expression [131-135].

MiR-17-92 FAMILY AND ORGANIZATION OF miRNA CLUSTERS

The miR-17-92 family of miRNA includes six miRNAs (miR-17, miR-18a, miR-19a, miR-20a, miR-19b-1, and miR92a), which share the same seed sequence, and are encoded tightly in an intron on human chromosome 13 [136, 137]. This cluster has two paralogs: the miR-106b-25 located on human chromosome 7, and the miR-106a-363 located on chromosome X. The miR-106a-363 cluster consists of six miRNAs: miR-106, miR-18b, miR-20b, miR-19b-2, miR92a-2, and miR-363. The miR-106b-25 cluster consists of three miRNAs: miR-106b, miR-93, and miR-25 [137]. The miR-106b-25 cluster consists of three miRNAs: miR-106b, miR-93, and miR-25 [137]. Members of the microRNA-17-92 family clusters are grouped into 4 sub-families, in which they share the same seed: miR-17 (miR-17, miR-20a, miR-20b, miR-106a, miR-106b, and miR-93), miR-18 (miR-18a and miR-18b), miR-19 (miR-19a and miR-19b), and miR-92 (miR-25, miR-92a, and miR-363) [137, 138].

REGULATION OF THE miR-17-92 FAMILY AND ITS ROLES IN CANCER

The miR-17-92 family are potential oncogenes: studies showed that this cluster facilitates tumor development in a mouse B-cell lymphoma model [139]. The oncogenic effects of this family are confirmed in many other types of cancers, such as lung, colorectal, liver and thyroid cancer [140-144]. Studies showed that the miR-17-92 family induces cancer through multiple mechanisms. For example, they induce proliferation through repression of Bim, a proapoptotic protein, and PTEN, a tumor suppressor [145]. High expression of miR-17-92 inhibits hypoxia-induced apoptosis because the key transcription factor involved in this process, hypoxia-inducible factor 1 α (HIF-1 α), is a direct target [143, 146]. MiR-17-92, and miR106b down-

regulate CDKN1A (p21Waf1/Cip1), a well-known tumor suppressor, which stops cell proliferation by suspending the cell-cycle progression [147, 148]. Myc is the factor that transactivates the cluster through binding to the promoter regions [149]. The E2F family of transcription factors also up-regulate miR-17-92 expression through direct binding to its promoter [150, 151]. In an interesting twist, miR-17 and miR-20 come back to inhibit translation of E2F1, E2F2, and E2F3 [149-151].

Table 1. miRNAs associated with cancer and their known targets

miRNA	Cancer association	Function	Targets	References
miR-15a miR-16-1	B-cell lymphocytic leukemia	TS	BCL2, MCL1, CCND1, WNT3A	[152-154]
miR-122	Breast, liver cancer	TS	ADAM17, IGF1R	[155-157]
miR-143	Pancreatic, colorectal, prostate cancer	TS	GEF1, GEF2, Ras	[158-160]
miR-144	Colorectal cancer	TS	mTOR	[161]
miR-155	Leukemia	OC	HDAC4	[162]
Let-7 family	Lung cancer	TS	HMGA2, Ras	[93, 94]
miR-21	Colorectal and lung cancer	OC	PTEN	[21, 163]
miR-27a	Acute leukemia	TS	4-3-3 theta	[164]
miR-17-19 family	Lung cancer	OC	PTEN, Bim, CDKN1A (p21Waf1/Cip1), E2F	[145, 148, 150]
miR-106b-25	Breast cancer, Prostate cancer	OC	Smad7 p21	[165], [166]
miR-182	Ovarian cancer	OC	BRCA1, HMGA2, FOXO3	[167]
miR-200c	Ovarian cancer, breast cancer	TS	TUBB3 (class III beta-tubulin gene), TrkB, NFkB	[168], [169]
miR-23b	Prostate cancer	TS	Src kinase, Akt	[170]
miR-218	Cancer metastasis to bone Gastric cancer	OC/TS	Wnt inhibitors: SOST (Sclerostin), Dkkopf2 (DKK2), SFRP2 (Secreted frizzled-related protein2) Robo1 receptor	[171],[172]
miR-34c	Resistance to apoptosis induced by paclitaxel in lung cancer	OC	Bmf (Bcl-2-modifying factor), Myc	[173]
miR-302-367 cluster	Cervical cancer	TS	CyclinD1, Akt1, indirectly up-regulate p271, p21	[174]

OC- Oncogene, TS- Tumor Suppressor

CAUSES OF ALTERATIONS IN miRNA EXPRESSION

Chromosomal Instability

Large portions of miRNAs are located at cancer-associated genomic regions. These regions contain oncogenes, tumor-suppressor genes and fragile sites, which are sensitive to sister-

chromatid exchange, translocation, deletion and amplification. MicroRNA loci are also prone to have alterations in human cancers [175]. Furthermore, multiple miRNAs with roles in cancer are located in cancer fragile regions. For example, the cluster miR-17-92 is located at chromosome 13q31, a region amplified in B-cell lymphomas, malignant lymphomas and lung cancers [139, 140, 176].

Epigenetic Regulations

MicroRNAs are also subject to epigenetic regulations, processes which can be involved in tumorigenesis. Epigenetic alterations are changes in gene expression caused by factors other than DNA coding, including DNA methylation, histone modifications and miRNA regulation. Multiple genes encoding miRNAs are methylated in cancer progression, such as multiple myeloma and chronic lymphocytic leukemia [177, 178]. Histone modification is also reported to have an essential role in miRNA regulation in hepatocellular carcinoma [179]. Furthermore, simultaneous inhibition of DNA methylation and histone deacetylation with a combination of 5-aza-2'-deoxycytidine and 4-phenylbutyric acid (PBA) significantly changes miRNA expression in bladder cancer cells [180].

Abnormalities in miRNA Biogenesis Machineries

Since miRNAs regulate many crucial pathways to maintain normal biological functions, the regulation of miRNAs themselves is strictly controlled. After transcription, pri-miRNAs need to go through multiple steps in order to transform into mature and fully functional miRNAs, which can target and silence complementary mRNAs. MicroRNA microbiogenesis is a complex process involving multiple proteins, any alteration in such factors may lead to changes in miRNAs expression and furthermore, cancer.

Drosha

Drosha expression in cancer is controversial. In triple-negative breast cancer tissue, the expression of Drosha is reported to be significantly higher than in normal breast tissue [181]. The same pattern is also observed in ovarian serous carcinoma [182]. However, in another clinical study, Drosha mRNA and protein expression were shown to be reduced in epithelial ovarian cancer specimens [183] and nasopharyngeal carcinoma [184]. BRCA1 regulates miRNA biogenesis through interaction with Drosha [185]. The alterations of Drosha in cancer are usually coupled with changes in overall miRNA expression. However, there is not yet any report showing a correlation between pathological Drosha expression and any specific miRNA(s).

DGCR8

In order for Drosha to process pri-miRNA, it needs to form a complex with DGCR8, a double-stranded RNA binding protein [184, 186]. DGCR8 is encoded by a gene located in a region frequently deleted in DiGeorge syndrome, the most common genetic deletion syndrome in humans [187]. DGCR8 binds pri-miRNAs while Drosha cleaves them and the two proteins interact with each other and form a so-called microprocessor complex [188]. Interestingly, while DGCR8 is known to stabilize Drosha through protein-protein interactions, knockdown of Drosha increases both DGCR8 mRNA and protein levels in cells [188, 189]. This could be interpreted as a mechanism cells use to maintain certain levels of these important proteins in the miRNA biogenesis complex.

Exportin-5

After being processed by the microprocessor complex, pre-miRNAs are transported from the nucleus to the cytoplasm by Exportin-5, a nucleocytoplasmic transport factor. In order to transport pre-miRNAs, Exportin-5 creates a complex with RanGTP and migrates from the nucleus to the cytoplasm. In the cytoplasm, pre-miRNA is released when RanGTP is hydrolyzed to RanGDP, which will be transported back to the nucleus with Exportin-5 [190-193]. Exportin-5 is reported to have tumor suppressor features since cancer cells have a genetic defect in Exportin-5, leading to the accumulation of pre-miRNAs in the nucleus [194].

The Structure of Dicer

Dicer is an endonuclease III that cleaves pre-miRNA into its final products, miRNA and miRNA*. The protein structure of Dicer from N-terminal to C-terminal includes an ATPase/helicase domain, DUF283 domain, PAZ domain, RNaseIIIa and RNaseIIIb domain, and dsRBD domain (Figure 1a). The ATPase/helicase domain helps Dicer to differentiate RNA substrates through binding to their terminal loops. Deletion of the ATPase/helicase domain leads to equal enzyme activity on both pre-miRNA and dsRNA substrates, while wild-type Dicer has favorable activity toward pre-miRNA [195].

DUF283 is a function unknown domain [196]. The PAZ domain anchors the ds-RNA end for RNase cleavage; therefore, the distance between the PAZ domain and the active sites of the RNase III domains determines the size of Dicer products [195]. Besides that, the dsRBD domain in Dicer is required for dsRNA binding only when the PAZ domain is absent [195]. The RNase IIIb domain is required for miRNA cleavage while the RNase IIIa domain is preferred for miRNA* cleavage [197, 198] (Figure 1b).

Dicer in Early Development

Dicer is essential for development in the early stages [199, 200]. The deletion of the *DICER* gene can lead to deficient and abnormal sperm cell formation. [201]. Similarly, Dicer has

critical roles in meiosis of the female germline [202]. Dicer null oocytes appear to have non-efficient chromosome-microtubule engagement, triggering a spindle checkpoint and delayed arrest, which results in a failure in mitotic chromosome segregation [202]. *DICER* heterozygous mutant mice embryos are not viable [199]. Elimination of *DICER* during embryogenesis causes perinatal death with loss of skeletal muscle mass and abnormal myofiber morphology, thus arresting embryonic development before the body plan is configured [199, 203]. Heterozygous mutation of *DICER* leads to small and abnormal embryonic morphology [199]. More interestingly, *DICER* mutant embryos have reduced Oct4 expression, which is one of key components to maintain embryonic stem cell proliferation [119, 199]. Dicer is also important for the later stages of development. It plays crucial roles in the development of lung epithelial morphogenesis and the normal maintenance of the mature pancreas [204, 205]. Deletion of *DICER* in somatic cells such as ovarian granulosa cells, mesenchyme-derived cells of the oviducts and uterus resulted in female sterility and multiple reproductive defects [206].

Figure 1. The schematic structure of the human Dicer protein.

The Role of Dicer in Cancer

Alterations of Dicer expression are observed in multiple genetic diseases. For example, “DICER1 syndrome” is a term used to describe familial pleuropulmonary blastoma, a rare malignant lung tumor that occurs in children under age of 6 [207]. Results from sequencing of DNA from a large amount tumors show that germ-line mutations in the *DICER* gene are the main causes of pleuropulmonary blastoma. Besides that, mutations of *DICER* may lead to different types of tumors, preferentially cystic nephroma and ovarian Sertoli-Leydig tumors [207]. Germline mutation of *DICER1*, the gene encoding Dicer in human, plays an important

role in Embryonal rhabdomyosarcoma, the most common childhood soft tissue sarcoma and its somatic mutation may have certain influence on the cause of the disease [208].

Dicer is a haploinsufficient tumor suppressor, which means the deletion of one *DICER* allele leads to tumorigenesis while complete loss of *DICER* suppresses tumors [209]. Mouse models of human cancers show that deletion of one *DICER* copy reduces survival compared to controls and *DICER* deleted animals. In a *DICER* conditional knockout mouse model of lung cancer, tumor progression showed selection against complete *DICER* recombination, which means growing tumors consisted mainly of Dicer haplodeficient cells instead of Dicer wholly deficient cells. On the other hand, forced complete deletion of Dicer led to a significant decrease in tumor burden compared to tumors where one *DICER* allele remained (Figure 2).

Surveys of human tumors also showed frequent loss of one allele of the gene encoding *DICER* in several tumor types, including breast, kidney, liver, lung, ovarian, pancreas and stomach [209]. The expression of Dicer is altered in many types of cancer. In epithelial ovarian cancer, low Dicer mRNA expression is recorded in the majority of specimens [183].

Figure 2. Haploinsufficiency of Dicer in cancer.

Reduction of Dicer is also correlated to advanced tumor stage, poor prognosis and lower survival [183]. Low Dicer reduces the cells' ability to process siRNAs [183]. DNA sequencing of *DICER* showed several mutations from tumor samples but there is not enough evidence to prove that *DICER* mutations are associated with the reduction of Dicer mRNA expression [183]. In endometrioid endometrial cancer, lower Dicer transcription is associated with disease recurrence and worse disease free survival [210]. The cause of low Dicer expression in this type of cancer was neither gene deletion nor DNA methylation and still remains unknown [210]. A study on chronic lymphocytic leukemia, the most common leukemia, showed that lower Dicer expression is associated with more aggressive cancer stages based on Binet

clarification and higher prognostic factors, such as CD38 and ZAP-70 [211]. Furthermore, a reduction of Dicer is also believed to be one indicator of shorter overall survival and lower disease free survival [211].

Dicer is over-expressed in many human breast cancer cells but the pattern is not consistent across all breast cancer subtypes [212]. High expression of Dicer increases breast cancer resistant protein, which effluxes tamoxifen from cells and increases resistance to tamoxifen treatment [212]. Dicer expression is reported to be higher in triple-negative breast cancer, another type of breast cancer with very poor prognosis due in part to its absence of drug targets (e.g., ER, PR and HER2 receptors) [181]. Interestingly, high concentrations of Dicer protein in triple-negative breast cancer samples are detected in the nuclear compartment while in normal breast tissue it is located mainly in the cytosol [181]. Thus, it is hypothesized that in triple-negative breast cancer, there are changes in the subcellular localization mechanisms of Dicer [181]. On the other hand, Dicer tends to be down-regulated in the non-luminal (ER negative) subgroup of breast cancer through correlations with high histological grade, lack of Bcl-2, high proliferation and expression of basal-like markers [213]. Basal-like breast cancer is associated with high grade, poor prognosis and younger patient age, and is identified by specific markers, such as EGFR, CKs, CAV1, CAV2 and nestin [214, 215]. The loss of Dicer is linked with breast cancer malignancy and a possible cause of miRNAs down-regulation in breast cancer [216, 217]. However, low Dicer expression does not affect the outcomes of breast cancer adjuvant anthracyclin-based therapy [213]. In lung cancer, Dicer is reduced in invasive adenocarcinoma but over-expressed in non-invasive precursor lesions (atypical adenomatous hyperplasia and bronchioloalveolar carcinoma) areas [218]. It is suggested that the up-regulation of Dicer can be an early sign of lung peripheral adenocarcinomas [218]. In another lung cancer study, reduced expression of Dicer was reported to be associated with poor prognosis and a shorter postoperative survival [219]. The cause of Dicer reduction was not known but it appears to be another mechanism than DNA methylation in the promoter region of *DICER* [219].

Table 2. Dicer alterations in cancers

Types of cancer	Regulation of Dicer	References
Ovarian	Down	[183]
Endometrial	Down	[210]
Breast	Down/Up	[181, 212, 213]
Leukemia	Down	[211]
Lung	Down	[218, 219]
Colorectal	Up	[220]
Prostate	Up	[224]
Melanoma	Up	[226]

In contrast, in certain types of cancers, such as colorectal cancer, high expression of Dicer is associated with poor overall survival and low disease free survival [220]. Since a decrease in overall miRNAs is believed to happen frequently in more aggressive tumors, dysfunction of alternative miRNA processing pathways might be an explanation for the occurrence of up-regulated Dicer in certain types of cancer [220-223]. In prostate adenocarcinoma, overall miRNAs expression is increased and Dicer levels increase as a correlation with disease stage, lymph node status and Gleason score [224]. Since it is believed that luminal cells tend to be the

origin of prostate cancer, the observance that Dicer is overexpressed in neoplastic luminal prostate cells suggested that high Dicer level might be an early sign of cancer development, probably facilitating the overall up-regulation of miRNAs [224, 225]. Also in cutaneous melanoma there is an up-regulation of Dicer mRNA in tumor cells, especially metastatic melanoma specimens, which suggests that Dicer overexpression may be a biomarker of cutaneous metastatic melanoma [226].

Regulation of Dicer

Currently it is still unknown exactly what or how Dicer is regulated. However, evidence suggests that the change in Dicer expression levels could be a consequence of feedback loops in miRNA processing machinery. MicroRNAs are an important factor that regulates DICER. For example, let-7 directly down-regulates Dicer in multiple normal and cancer cell lines, both at the mRNA and protein level [227]. Sequencing results showed that members of the let-7 family are complementary to the 3' UTR region of DICER [227]. In fact, Dicer regulation is considered an intermediate step for let-7 to regulate other miRNA expression [227]. This result requires further investigation on whether let-7 acts as tumor suppressor gene through Dicer down-regulation.

Another miRNA family that directly targets Dicer is the miR-103/107 family [228]. Similar to the let-7 family, this direct targeting attenuates miRNA biosynthesis [228]. In contrast to the let-7 family, the miR-103/107 family is a biomarker for worse prognosis in breast cancer [228]. Since they are oncogenic miRs, Dicer down-regulation is an intermediate step before these miRNAs are capable of exerting oncogenic effects. For example, miR-103/107 can trigger the events of metastasis or epithelial to mesenchymal transition (EMT) [228]. In others words, in spite of the complicated expression patter of Dicer in breast cancer, it is the miR-103/107 family, not DICER, that should be targeted for cancer therapy.

Exportin-5, the factor responsible for miRNA transport across the nuclear membrane, also regulates Dicer post-transcriptionally [229]. Inhibition of Exportin-5 leads to the accumulation of Dicer mRNA in the nucleus and ultimately the reduction of cytosolic DICER mRNA and functional DICER protein [229]. Furthermore, an increase in pre-miRNA saturates Exportin-5, thus preventing Dicer mRNA transport to the cytoplasm for translation [229]. This event is suggested to be a cross-regulation mechanism in miRNA biosynthesis with the purpose of maintaining miRNA homeostasis inside the cells [229].

Beyond miRNA processing machineries, several different factors are shown to regulate Dicer. One study of multiple cell lines with different Dicer expression levels showed that Dicer protein is repressed by reactive oxygen species, phorbol esters, the Ras oncogene, Type 1 interferon and double-stranded RNAs [230]. These data suggest that Dicer has a role in the cellular stress response and proposed that interferons are regulators of Dicer proteins [230]. Metformin, a medication for diabetes, increases Dicer mRNA and thus protein expression levels [231]. Indeed, metformin enhances the binding of transcription factor E2F3 and inhibits the transcriptional repressor E2F5 at the promoter of the Dicer gene [231]. Metformin exerts its anticancer effects by up-regulating Dicer and multiple miRNAs, many of which are involved in metabolism [231].

Interestingly, a recent study reported that Dicer has other functions beyond miRNA microbiogenesis. In fact, Dicer processes transcripts from RD2 Alu repeats into small RNAs

(28-65nt), which will target critical stem-cell RNAs, including Nanog mRNA [232]. These data suggest that our understanding of this multifaceted protein is incomplete; further research is needed to identify the complex nature of Dicer.

Argonautes

After being processed by Dicer, the miRNA:miRNA* duplex is loaded into the RISC (RNA-induced silencing complex) [233-235]. MicroRNA* is primarily released (although in some systems it may exert significant biological effects) while miRNA is used to target mRNA for cleavage [236, 237]. Argonaute proteins (AGO1-4) are essential components of the RISC complex. Even though all four AGOs can repress mRNA expression, only AGO2 plays an essential role in mRNA cleavage [238, 239]. AGO1 and AGO2 are shown to up-regulated in serous ovarian cancer [182]. Furthermore, promoting expression and activation of AGO2 has positive effects on cancer by enhancing multiple tumor-suppressive miRNAs [240].

Chapter 104

THE ROLE OF THE EPIDERMAL GROWTH FACTOR RECEPTOR AS A THERAPEUTIC TARGET IN GLIOBLASTOMA AND OTHER MALIGNANCIES

Andrej Pala^{*}, Christian Rainer Wirtz and Marc-Eric Halatsch[†]

Department of Neurosurgery, University of Ulm School of Medicine, Ulm, Germany

ABSTRACT

Glioblastoma multiforme (GB) is the most common primary brain tumor among adults. Rapid tumor progression and diffuse invasion of brain tissue results in a poor prognosis despite advances in the understanding of the tumor's molecular biology. Recently, targeted therapy has been introduced as a potential therapeutic option in several types of cancer. Dysregulation of the epidermal growth factor receptor (EGFR) has been identified in a number of different malignant tumor entities, such as GB. Despite promising reports from preclinical studies, clinical trials yielded no significant improvement of outcomes of patients with GB who were treated with anti-EGFR-targeted agents. Molecular mechanisms underlying resistance to this treatment approach have become a focus of scientific efforts in the last years. The variations and complexity of EGFR signaling pathways demand a composite therapeutic strategy to quench alternative signaling routes which otherwise might enable cancer cell survival and subsequently tumor progression.

INTRODUCTION

In the last years, molecularly targeted therapy has rapidly evolved. Within this concept, the epidermal growth factor receptor (EGFR) became a common therapeutic target in many cancers [1-3]. The EGFR is a 170 kDa single-chain transmembraneous glycoprotein transmitting signals for various pathways, thereby playing an important role in cellular proliferation [1,2].

Glioblastoma (GB) is the most common primary brain tumor among adults. Despite intense research efforts, the prognosis of patients with GB remains poor with current standard therapy consisting of tumor resection, adjuvant irradiation and temozolomide [2-4]. The EGFR is the most frequently altered oncogene in GB [3]. While the clinical use of small-molecule EGFR tyrosine kinase (TK) inhibitors has fallen short of expectations in patients with GB [4], a better understanding of molecular signaling pathway interactions may allow for the development of new rational therapeutic strategies to overcome intrinsic and/or acquired resistance of GB cells towards EGFR inhibition.

THE EGFR AND ITS ROLE IN TUMORIGENESIS

The human epidermal growth factor receptor (HER) family consists of four structurally related receptors, *i.e.*, HER1/EGFR, HER2/neu, HER3 and HER4. They are composed of internal, transmembraneous and external domains. The EGFR is activated by various ligands, most importantly epidermal growth factor (EGF) and transforming growth factor (TGF)- α [1,2]. Dimerization is a crucial step in HER signaling pathway activation. Both homo- and heterodimerization are possible, allowing variable receptor combinations [5]. Formation of dimers results in the activation of EGFR's internal TK domain with subsequent phosphorylation of tyrosine residues which, in turn, promote the activation of cytoplasmic downstream signaling routes. The phosphorylated tyrosine residues bind to signaling molecules with SRC homology 2 (SH2) which promote further intracellular signaling. The signalling routes involve activation of RAS-RAF-mitogen-activated kinase (MAPK), phosphatidylinositol-3-kinase (PI3K), phospholipase C γ (PLC γ) or Janus-activated kinase (JAK)-2. These molecular signaling mechanisms regulate various cellular processes involving proliferation and differentiation (Figure 1) [1-5].

Growth factor receptor binding protein 2 is a docking protein that is able to bind to activated EGFR-TKs, thereby creating complexes with the guanine nucleotide factor son of sevenless (SOS) through a SH3 domain. Activated SOS mediates the exchange of guanosine diphosphate (GDP) for guanosine triphosphate (GTP) in RAS that induces the activation of the serine/threonine protein kinase RAF, which, in turn, phosphorylates another serine/threonineprotein kinase, MEK. MEK activates MAPK that targets nuclear transcription factors, such as the E-Twenty-Six (ETS) family factors FOS, JUN and SLUG (SNAI-2) and hereby regulates cellular proliferation or differentiation [2,6]. The other signalling pathway mediated by EGFR is activated through PI3K, which forms phosphatidylinositol-3,4,5-triphosphate (PIP3) that further (through activation of AKT also known as PKB (protein kinase B)) indirectly phosphorylates the mammalian target of rapamycin (mTOR), which is playing a crucial role in cellular proliferation [7]. In addition, AKT is involved in the regulation of apoptosis through inactivation of proapoptotic proteins, such as BCL-2-associated death protein (BAD) or caspase 9. The next well-known signaling cascade promoted through EGFR-TK activation is the PLC γ pathway. Phospholipase C γ produces diacylglycerol (DAG) and inositoltriphosphate (IP3) through hydrolysis of phosphatidylinositol-4,5-bisphosphate (PIP2). Inositoltriphosphate binds to the IP3 receptor that triggers the influx of calcium ions from the endoplasmic reticulum and thereby triggers the activity of various proteins within the cytoplasm (Figure 1) [6,8].

These diverse signaling routes, mediated through EGFR activation, possess various messengers, alteration of which may contribute to the dysregulation of precisely coordinated signaling networks. Moreover, the plasticity of tumor cells may result in preference and potentiation of parallel signaling pathways and hereby contribute to the development of resistance to targeted therapy. Thus, simultaneous targeting of more signaling routes could lead to better inhibition and control of tumor cell proliferation.

Figure 1. EGFR-mediated signaling cascades. DAG – diacylglycerol, EGF – epidermal growth factor, FGF – fibroblast growth factor, HGF – hepatocyte growth factor, IGF – insulin-like growth factor, IP3 – inositoltriphosphate, MAPK – mitogen-activated protein kinase, MEK – mitogen-activated protein kinase kinase, mTOR – mammalian target of rapamycin, PI3K – phosphatidylinositol-3-kinase.

Amplification and overexpression of the EGFR gene is frequently present in GB and other malignancies such as breast cancer or non-small cell lung cancer (NSCLC), contributing to unregulated cell proliferation [3,4,9]. Other mechanisms that lead to functional alteration of the EGFR are autocrine or paracrine overproduction of ligands and deletion-mutation of the receptor. The most common mutation, with an incidence of up to 58% in GBM, is EGFR variant (v)III which results from in-frame deletion of 801 base pairs in the DNA sequence encoding the extracellular receptor domain [3,4,9]. This mutation yields a constitutively activated receptor without any control mechanisms. In addition, mutations in the carboxyl terminal domain, referred to as EGFRvIV, have been described. Their activity exhibits significant tumorigenic potential [10].

The EGFR-TK inhibitors gefitinib and erlotinib are small molecules that compete with adenosine triphosphate (ATP) for intracellular TK domains. Hereby they prevent TK phosphorylation and inhibit downstream signaling that engages intracellular MAPK and PI3-K/AKT pathways. Gefitinib has been used for the treatment of NSCLC [11]. Even if the initial results were disappointing, further analysis enabled specification and selection of patients who harbour mutations of the intracellular EGFR domain that confer significant treatment

responses. Thus, gefitinib became an option in advanced and metastatic NSCLC. Analysis of structural receptor changes in both NSCLC and GB has revealed different types of alterations. Mutations found in NSCLC that confer response to erlotinib affect almost exclusively the intracellular EGFR domain whereas mutations in the external domain are mostly present in GB. Accumulating evidence suggests that the type of mutation that is characteristic for GB does not confer sensitivity to erlotinib, in contrast to EGFR mutations present in NSCLC [12,13]. Erlotinib binds to the active conformation of the TK domain that is less effective in GB. The absence of ATP-binding domain mutations in GB may be the explanation for failure of erlotinib against this disease. In contrast, lapatinib, a dual HER1/2 inhibitor, interacts with the inactive conformation of the TK domain, inducing cell death in EGFR-mutated GB cells. Almost complete inhibition of EGFR is required to achieve cell death induction [12,13]. The concentration of lapatinib that effectively leads to EGFR inhibition in GB cells *in vivo* remains unclear, and this may contribute to actually disappointing clinical results that show no clinical benefit of this approach [12-15]. It has been reported that low doses of dual EGFR and HER2 inhibitors result in better overall survival in xenograft models. In contrast, high-dose treatments may evoke rapid activation of alternative signalling routes and hereby enhance the development of resistance and tumor invasion [14,15].

The EGFRvIII and EGFRvIV contribute significantly to the activation of distinct signaling routes. The variability and complexity of this signaling enhance the adaptability of tumor cells [10]. The deletion-mutants EGFRvIII and EGFRvIV are stabilized by heat shock protein (HSP) 90 [16]. This is a common intracellular protein that guides folding and intracellular distribution of many other proteins, such as AKT or RAF-1. Heat shock protein 90 interacts with other co-chaperones and hereby forms and modulates protein complex conformation. Its action is attached to ATP hydrolysis, which ultimately results in conformational changes of other proteins. Heat shock protein 90 together with co-chaperone p50^{cdc37} build complexes with nascent EGFR and HER2/neu. Mature EGFR dissolves from Hsp90-p50^{cdc37} [16,17]. HER2/neu requires association with Hsp90-p50^{cdc37}. This molecular dependence might be another possible target that could bring about new therapeutic options [17].

Monoclonal antibodies such as cetuximab have been investigated as possible inhibitors of the EGFR signaling pathway [18,19]. Cetuximab binds to EGFR with high affinity and blocks further signal transduction within the EGFR-mediated signaling route. This effect contributes to the inhibition of cell cycle progression and angiogenesis. Moreover, cetuximab may induce apoptosis through overexpression of BAX and reduction of BCL-2 activity. It has been reported that in combination with other chemotherapeutic drugs, cetuximab increases the frequency of apoptosis *in vitro* and *in vivo*. However, the insufficient penetration of the blood-brain barrier may impede a relevant therapeutic effect [18,19].

The scientific efforts of the last few years were preferably concerned with the kinase-related activity of EGFR. However, TK-independent EGFR activation may play a significant role within cellular signaling pathways as well and may constitute an important reason for clinical failure of EGFR-TK inhibition in GB. Kinase-independent activity of EGFR is involved in cellular energy metabolism by maintaining intracellular glucose levels that prevent cells from undergoing cell death [20]. This observation is supported by the fact that the inhibition of EGFR phosphorylation results in diminished glucose uptake. However, the level of intracellular glucose does not reach the low concentration found in cells with entirely inactive EGFR. It has been reported that EGFR stabilizes the sodium-glucose linked transporter

(SGLT)-1 and hereby maintains the cellular uptake of glucose that is necessary for cell survival [20]. The SGLT-1 is a transmembraneous protein that enables glucose transport across the cell membrane. The inhibition of EGFR-TK activity provides deceleration of cell proliferation, but in the majority of cases does not result in cell death [20].

EPITHELIAL-TO-MESENCHYMAL TRANSITION

Epithelial-to-mesenchymal transition (EMT) may serve as another possible explanation for cell survival despite the inhibition of EGFR. Generally, EMT is a sequence of molecular signaling events that ultimately lead to increased invasiveness and dissemination of tumor cells [21,22]. These molecular changes play a crucial role in many physiological processes such as wound healing or organ development. Under pathological conditions, EMT is considered an important factor responsible for cancer progression. During EMT, cells lose their epithelial characteristics and acquire mesenchymal features such as the expression of fibronectin and vimentin [4,9,21,22]. These steps contribute to the acquisition of the biologically aggressive mesenchymal phenotype. Numerous signaling pathways have been implicated in EMT during cancer progression. For example, E-cadherin is a cell surface protein that mediates cell-to-cell contact. This main epithelial surface protein is involved in the regulation of critical processes in the development of epithelium [21,22]. Thus, minimal alterations in the regulatory network may significantly influence the overall physiology of the epithelial cell.

E-cadherin belongs to a large superfamily of cell-to-cell, calcium-dependent, homophilic adhesion molecules that are specified according to the tissue in which they are preferably formed. In general, cadherins build dimers that bind through their extracellular domains to cadherin dimers of neighbouring cells. The intracellular region is anchored to the plasma membrane and binds to the cytoskeleton through catenins. In particular, β -catenin and p120 catenin mediate the intracellular E-cadherin contact with the cytoskeleton, either directly or through other proteins, such as vinculin or β -actinin [9,21,22].

Epithelial cells are contact-inhibited through cell cycle arrest after reaching monolayer formation. Dysregulation of E-cadherin results in the dissolution of tight junctions, so that neighbouring cells lose their connections [9,21-23]. In addition, the loss of apico-basal polarity together with reorganisation of cytoskeletal components potentiates the cellular transformation from a cuboidal to a spindle-like shape. The anti-migratory and anti-proliferative effects of E-cadherin decrease. During organ development or wound healing, these processes are clearly coordinated and well-defined. Under pathological conditions, dysregulation of the signaling network occurs, facilitating the progression of cell transformation and behavioural modulation [21-23].

E-cadherin expression can be altered in different manners. Production of growth factors by the microenvironment may result in E-cadherin downregulation. Furthermore, overexpression of EGFR has a direct influence on E-cadherin function. Intracellular E-cadherin complexes can become direct targets of TKs. Phosphorylated complexes destabilize, and the strength of cell-to-cell adhesion weakens. Moreover, phosphorylation of E-cadherin complexes may be regulated through cytoplasmic kinases, such as SRC [21-23].

E-cadherin activates different signaling pathways, such as MAPK or PI3-K, after formation of cell-to-cell contact [9,21-23]. Additionally, E-cadherin can activate EGFR in the absence of

ligand and hereby trigger its signaling pathways [24]. This mechanism may significantly enhance cell proliferation or survival.

Alterations of several transcription factors and oncogenes contribute to the complex multilevel molecular transformation involved in EMT. The key transcriptional factors are SNAI-1/2, zinc finger E-box (ZEB)-1/2, TWIST and WNT/ β -catenin [21-24]. Their activity promotes loss of epithelial characteristics within cells and progressive acquisition of the mesenchymal phenotype. TWIST-1 is a helix-loop-helix protein that binds to DNA as a heterodimer, activates the mesenchymal marker N-cadherin and inhibits the expression of E-cadherin [4]. Specific inhibition of TWIST expression leads to reduction of glioma invasion *in vitro* [4,25]. Moreover, TWIST is involved in the regulation of p53-regulated apoptosis. The prevention of growth arrest further promotes the invasive phenotype of tumor cells, especially in GB [4,25]. This mechanism may lead to increased resistance to different therapeutic agents and ultimately to failure of targeted therapy.

SNAI-1 represents a transcriptional repressor that targets the expression of E-cadherin and belongs to a family composed of three members. SNAI-1 contains a SNAG domain which plays a crucial role for SNAI-1 activity. The repression of E-cadherin potentiates cellular invasion and migration [9,21-23]. Additionally, SNAI-1 induces the activation of matrix metalloprotease (MMP)-2. Matrix metalloproteases belong to a large family of zinc-dependent endoproteases that dissolve extracellular matrix proteins. This effect contributes to the increased invasiveness and aggressiveness of cells with the mesenchymal phenotype [9, 21-23].

Signal transducer and activator of transcription (STAT) signaling routes play an important role in EGFR-mediated signal transmission. Dysregulation of this pathway is associated with many human malignancies. Signal transducer and activator of transcription (STAT) proteins are located in the cytoplasm of all dividing cells. The STAT family contains seven protein members (STAT-1-4, STAT-5a, STAT-5b, STAT-6) which interact with different cytokines and various downstream signaling molecules as well as with EGFR autophosphorylation sites [26]. Cytokine receptors, such as interleukin (IL)-6, possess no intrinsic TK activity. They initiate Janus activated kinase (JAK) family members that mediate signaling to STAT molecules through phosphorylation of specific tyrosine residues. This process results in homo- or heterodimerisation of STAT molecules via SH2 domains. These complexes translocate into the nucleus, bind to specific DNA sequences and influence STAT genes that are associated with cell proliferation, differentiation, motility and apoptosis. Signal transducer and activator of transcription dimers can also be formed directly through phosphorylation by EGFR-TKs. Additionally, the activation via cytoplasmic SRC or Abelson murine leukemia viral oncogene homolog (ABL)-1 kinases is possible as well [26,27].

Signal transducer and activator of transcription-3 expression is typically associated with GB, and STAT-3 is activated by phosphorylation of tyrosine residue Y705 or by serine phosphorylation at the domain S727. The extent of STAT-3 activation correlates with glioma grade [27]. Activated STAT-3 translocates into the nucleus and regulates the expression of various genes, such as PIM-1, c-MYC, cyclin D2 or cyclin A, that are involved in cell cycle progression, oncogenesis, and apoptosis. Increased expression of TWIST results in the activation of EMT signaling. In addition, STAT-3 is able to interact with EGFRvIII and contributes to the malignant transformation of astrocytes in gliomas [27,28]. Signal transducer and activator of transcription-3 and EGFR-EGFRvIII promote together the activation of the pro-inflammatory gene cyclooxygenase (COX)-2 at the nuclear level [28]. Cyclooxygenase-2

is overexpressed in various malignancies such as NSCLC. Its activity may promote resistance to apoptosis and through the activation of angiogenesis confer invasiveness of tumour cells. Prostaglandin E-2 (PGE-2) as the main effector of COX-2 reduces the expression of E-cadherin via ZEB-1 and SNAI-1. Signal transducer and activator of transcription-3 contributes to the regulation of different signaling pathways and has an important influence on EMT and the cell cycle. It may represent an important strategic factor that could become an additional molecular target in the therapy of GB [27,28].

Signal transducer and activator of transcription-5 is activated by numerous cytokines, such as IL-2, IL-3, IL-5, erythropoietin, granulocyte macrophage colony stimulating factor (GM-CSF) or growth hormone. Upon activation and translocation into the nucleus, STAT-5 dimers regulate genes that are involved in apoptosis, e.g., the BCL genes. Constitutive STAT-5 activation has been implicated in hematopoietic malignancies and various solid tumors, such as breast or prostate cancer [29].

The general regulatory network may be modified through EMT epigenetically. For example, methylation of histones or DNA may significantly influence activation of genes associated with cell cycle regulation or apoptosis. CDH-1 represents the gene that encodes E-cadherin. It has been reported that SNAI-1, which is an important EMT-associated repressor of E-cadherin, activates DNA-methylating enzymes and simultaneously histone demethylases [30].

Transforming growth factor (TGF)- β is a protein that takes part in the regulation of cell proliferation and differentiation. Transforming growth factor- β contributes to EMT induction and activates many routes that result in the mesenchymal transformation of cells, e.g., SNAI, ZEB and TWIST which are commonly associated with tumor invasion. Additionally, TGF- β is associated with apoptosis induction via the SMAD pathway. Transforming growth factor- β enhances signaling in the MAPK and PI3K-AKT pathways and hereby mediates the expression of SNAI-1 and SNAI-2 [31]. Subsequently, the expression of fibronectin, vimentin and other proteins associated with the mesenchymal phenotype is increased. In contrast, the expression of E-cadherin decreases. SNAI proteins influence the activation of RHO and RAC. This action reduces adhesiveness and stimulates motility of cells. RHO is a small signaling G protein that belongs to the RAS superfamily of proteins that are involved in the regulation of actin [31].

EXTRACELLULAR MATRIX AND MICROENVIRONMENT

The extracellular matrix (ECM) is separated from epithelial cells by the basement membrane. As a result of malignant transformation and tumor dissemination, the integrity of the basement membrane destabilises. After elimination of this barrier, different signaling molecules produced by the ECM interact with epithelial cells and hereby activate cell responses at the nuclear level that are normally inhibited through the basement membrane. Besides the changes within cell-to-cell adhesion, alterations of cell-to-matrix adhesions determine the invasive features of cells [21-24,31]. Integrins build a large protein family involved in cell-to-matrix interactions [32,33]. They form heterodimer receptors for ECM proteins such as collagen, laminin or fibronectin [31,32]. Intracellular components of integrins cooperate with different TKs such as EGFR-TK. This signaling leads ultimately to actin polymerisation and phosphorylation of focal adhesion kinase (FAK), and binding residues for PI3-K, SRC or PLC γ

form [31,32,34]. Within this context, cell migration is induced by ECM via integrins. Dysregulated EGFR signaling subsequently dephosphorylates and inactivates FAK [34]. This process increases the migratory potential of solitary tumor cells. They detach from the ECM, disseminate and create new metastasis. On the other hand, integrin-mediated alignment may be an important step for the inverted process, called mesenchymal-to-epithelial transition (MET) [21-23]. Tumor cells acquire some adhesive properties again and form new solid masses. It has been reported that EGFRvIII interacts with integrins and hereby promotes metastatic progression [35].

MECHANISMS OF RESISTANCE TO CURRENT THERAPY OF GB

Within current GB studies, cancer stem-like cells (CSC) have received much attention. They exhibit a high tumorigenic potential in combination with relatively low proliferative activity. Cancer stem-like cells express the CD133 (prominin-1) gene which is a characteristic feature of all normal neural stem cells [36,37]. Additionally, CSCs demonstrate stem cell properties, such as colony formation or multilineage potency. Glioblastoma typically presents as a diffuse tumor that invades normal brain tissue and frequently recurs or progresses after radiation therapy. Cancer stem-like cells possess high resistance to radiation and chemotherapy [36,37]. A great extent of activation of DNA repair mechanisms represents a relevant factor that may contribute to this phenomenon. Moreover, the high self-renewal activity of cells expressing CD133 stimulates initiation, growth, invasion and recurrence of GB. Moreover, CSCs overexpress angiogenic vascular endothelial growth factor under hypoxic conditions [36-38]. A hypoxic microenvironment plays a crucial role in the recruitment and growth of stromal cells that consecutively support tumor progression.

Compensatory activation of HER2/neu and HER3 may result in increased resistance of CSCs against the inhibition of EGFR signaling [36,37]. Based on this observation, lapatinib as a dual EGFR/HER2 inhibitor yielded significantly better antiproliferative responses compared to cetuximab and other anti-EGFR-targeted agents. In the absence of an exogenous EGF stimulus, MAPK and AKT signaling remained constant through the activation of alternative signaling mediated by HER2/neu and HER3. In contrast, lapatinib decreases AKT and MAPK downstream signalling more effectively. This example provides a possible explanation for GB resistance to anti-EGFR-targeted monotherapy [36]. The multiple targeting of HER family members is an option which could potentially overcome resistance to anti-EGFR therapy and improve the clinical outcome of patients with GB.

Normal stem cells play a crucial role in differentiation, development and organogenesis. Transcription factors, such as NOTCH, ID1, SOX2 or OCT4 have been implicated in the regulation of balance between stem cell proliferation and differentiation. Dysregulation of this balance contributes to tumorigenesis. Myeloid Elf-1-like factor (MEF) is a member of the EST family of proteins. Myeloid Elf-1-like factor downregulates p53 through overexpression of MDM2 [36-38]. This process reduces activation of INK4a and promotes phosphorylation of the retinoblastoma protein. SOX2 is a high mobility group (HMG) box transcription factor that contributes to the self-renewal of stem cells. Moreover, its activity has been described in different malignancies and in GB. SOX2 is a direct target of MEF and through this action may potentiate stem-like features of tumor cells [37].

The WNT signaling route is related to EMT as well. WNT is associated with β -catenin. The transmembraneous Frizzled receptor is activated via WNT protein and targets Dishevelled, which inhibits glycogen synthase kinase (GSK)-3 β and thereby reduces the phosphorylation and degradation of β -catenin. Disinhibited β -catenin translocates into the nucleus and binds to T-cell factor (TCF) and to lymphoid enhancer factor (LEF)-1 [38]. This signaling activates various genes that are associated with EMT, such as SNAI-2 or JUN. In addition, the expression of proteins with mesenchymal characteristics increases, resulting subsequently in the development of a more aggressive cellular phenotype. The WNT/ β -catenin pathway induces cell migration which is important not only for embryonic development but for tumor progression as well. Additionally, this signaling route may lead to the acquisition of stem-like features in GB cells, which, in turn, increases the resistance to current standard therapy and may play a crucial role in tumor recurrence. Overexpression of the signaling regulator Frizzled 4 potentiates signalling within the WNT route and consecutively may influence the development and maintenance of CSCs [39].

CONCLUSION

The complexity and structural density of the molecular pathways involved in EMT result in fast and dynamic changes in the pathophysiology of GB. The inhibition of one downstream pathway may potentiate alternative signaling routes and challenge or induce adaptation mechanisms of tumor cells. The combination of various inhibitory mechanisms could lead to a better control of dysregulated signaling pathways in the future. Additionally, this approach might be effective in preventing the development of tumor cell resistance. The definition of mutational variations and their systematic conquering at different levels together with the identification of patients who would probably benefit from targeted therapy is urgently needed. The pharmacokinetics of anti-EGFR-targeted agents remains another challenge to be addressed. Future stepwise improvements in the areas outlined above hold the potential for progressively improving the prognosis of patients with GB.

Chapter 105

TUMOR SUPPRESSORS INVOLVED IN DNA REPAIR AND CARCINOPREVENTION

Yasuko Kitagishi and Satoru Matsuda*

Department of Environmental Health Science,
Nara Women's University Kita-Uoya Nishimachi Nara, Japan

ABSTRACT

Cells possess a machinery to maintain the genomic integrity in response to the DNA damage. Mutations in several genes whose product improve the effects of DNA damage are known to predispose to develop a cancer. Under the genotoxic conditions, cells do not progress into S or M phase by activating DNA damage checkpoint, which acts as a process to transmit information from the damaged DNA lesions to cell cycle regulators. Tumor development may be accelerated by disruption of the balance between cell proliferation and the cell cycle regulation, which is maintained through regulations of various signal transduction pathways. It has been demonstrated that the signal transduction pathways are built on complicated networks between oncogenes and tumor suppressor genes such as p53 and its downstream factors. When the tumor suppressors lose their function, the cell may progress to cancer in combination with other genetic changes. Tumor suppressors regulate diverse cellular activities including DNA damage repair, cell proliferation, cell differentiation, cell migration, and programmed cell death. A better understanding of the cellular response to DNA damage will not only inform our knowledge of carcinogenesis but also provide better therapeutic opportunities.

Keywords: DNA repair, p53, BRCA1, PTEN, PI3K, AKT, ROS, cell signaling

ABBREVIATIONS

ATF2:	activating transcription factor 2
ATM:	ataxia telangiectasia-mutated
DSBs:	DNA double strand breaks
ERK:	Extracellular Signal-regulated Kinase
MAPK:	mitogen activated kinase
NF- κ B:	nuclear factor kappaB
mTOR:	mammalian target of rapamycin
PI3K:	phosphoinositide-3 kinase
PIP2:	phosphatidylinositol 4,5- bisphosphate
PIP3:	phosphatidylinositol 3,4,5-triphosphate
PTEN:	phosphatase and tensin homologue deleted on chromosome 10
PPAR:	peroxisome proliferator-activated receptor
PTP:	protein tyrosine phosphatase
ROS:	Reactive oxygen species
SAPK:	stress-activated protein kinase
TGF:	transforming growth factor

1. INTRODUCTION

Increased level of the oxidative stress results in cellular damage. To deal with DNA damages, cells are equipped with the multiple DNA repair mechanisms, which provoke a process to inhibit cell cycle progression and to induce DNA repair [1, 2]. One mechanism by which the oxidative stresses are thought to exert the effects may be through the reversible regulation of target molecules including several kinases, PI3K, and PTEN [3]. In addition, the main DNA damage recognition molecule is ataxia telangiectasia-mutated (ATM), which is a checkpoint kinase that phosphorylates a number of proteins including p53 and BRCA1 in response to the DNA damage (Figure 1). The p53 protein is a key transcription factor that regulates several signaling pathways involved in the cellular response to genome stress and DNA damage. Through the stress-induced activation, p53 triggers the expression of target genes that protect the genetic integrity of cells [4, 5]. A number of studies have demonstrated an antioxidant role for tumor suppressor proteins, activating the expression of some antioxidant genes in response to the oxidative stress. The tumor suppressors regulate diverse cellular activities including DNA damage repair, cell cycle arrest, cell proliferation, cell differentiation, migration, and apoptosis [6]. Normal cells show an exquisite balance among these various mechanisms of DNA repair. Mutations in the ATM have been associated with increased risk of developing a cancer. In addition, it is well known that mutations in the p53 and BRCA1 tumor suppressor genes account for a certain amount of cancers.

Figure 1. Schematic representation of the Cell proliferation, DNA repair and Growth arrest signaling pathways. Examples of the molecule known to act on the regulatory pathways are shown.

Figure 2. Schematic diagram indicating the domain structures of the p53, BRCA1, and PTEN proteins. The functionally important sites including the sites are also shown. Note that the sizes of protein are modified for clarity. TA= transactivation domain; PxxP= proline rich region; RING= (Really Interesting New Gene) finger domain, NLS= Nuclear Localization Signal, BRCT= BRCA1 C Terminus; C2 domain= a protein structural domain involved in targeting proteins to cell membranes; PDZ= a common structural domain in signaling proteins (PSD95, Dlg, ZO-1, etc.).

Genomic instability is often linked to DNA repair deficiencies. Standard DNA repair pathways available in mammalian cells include homologous repair, nonhomologous end joining, single strand annealing and so on. Those are different pathways that repair DNA double strand breaks (DSBs) [7]. The DNA repair is essential for the survival of both normal and cancer cells. An elaborate set of signaling pathways detect the DSBs and mediate either survival on the DNA repair or apoptotic cell death [8, 9]. The DNA damaging agents for cancer therapies are potent inducers of cell death triggered by the apoptosis. Recent advances in basic science have led to a better understanding of the molecular events important in the pathogenesis of cancer. In the present review, we summarize the function of prominent DNA repair molecules and the tumor suppressor gene products, p53, BRCA1 and PTEN (Figure 2), at a viewpoint of carcinogenic DNA damage and cellular response in cancer.

2. RELATIONSHIP BETWEEN DNA REPAIR AND CARCINOGENESIS

The DNA repair system is a highly conserved DNA editing process that maintains genomic fidelity through the recognition and repair of the damaged nucleotides. Genetic defects in DNA damage response genes and/or down-regulation of the DNA repair mechanism promote genomic instability, which can lead to carcinogenesis [10]. Cells are then equipped with multiple DNA repair mechanisms to the maintenance of genomic stability. The main DNA damage recognition molecule is ATM [11], which is a checkpoint kinase that phosphorylates a number of proteins in response to DNA damage including p53 and BRCA1 (**Figure 1**). Schematic structures of these important molecules are shown in Figure 2. An additional consequence of defective DNA repair is cellular hypersensitivity to DNA damaging agents [12]. Inhibition of DNA repair pathway seems to block the mechanisms that are required for survival in the presence of oncogenic mutations. Epigenetic mechanisms such as histone modifications and DNA methylation have been evaluated with a view for enhancing the cancer therapy via the regulation of the expression of genes involved in DNA repair [13]. Through the stresses-induced activation, p53 triggers the expression of the target genes that protect the genetic integrity of cells. The p53 gene is frequently mutated in multiple cancer tissues, suggesting that p53 plays a critical role in preventing cancers. Mutant p53 can be classified as a loss-of-function or gain-of-function protein depending on the mutation-type [14]. Wild-type p53 is inactive under normal physiological conditions and is activated in response to various types of DNA damaging stresses. The p53 activation may lead to regression of existing neoplastic lesions and therefore may be important in developing cancer prevention [15]. Failure of the DNA repair functions leads to p53-mediated induction of apoptotic cell death [16]. In this way, the p53 has been known to play a central role in maintaining a stable genome through its role in DNA repair, and apoptosis.

BRCA1 also fulfills the criteria for a tumor suppressor gene whose function is required to block cancer development. The mutation is associated with increased genomic instability in cells, which accelerates the mutation rate of other critical genes. Studies have established functional roles for BRCA1 in DNA damage signaling, DNA repair processes, and cell cycle checkpoints [17]. Consistent with these functional roles, cells deficient for *BRCA1* exhibit severe genomic instability and chromosomal aberrations. *BRCA1* cDNA encodes for 1863 amino acids protein with an amino terminal zinc ring finger motif and two putative nuclear

localization signals (Figure 2). The amino-terminal domain possesses E3 ubiquitin ligase activity [18] and the carboxyl-terminal domain is involved in binding to specific phosphoproteins [19]. BRCA1 becomes hyperphosphorylated after exposure to the DNA damaging agents, and the specific function of BRCA1 seems to be regulated by the phosphorylations [20]. Hence the DNA repair levels may be a novel therapeutic modality in cancer. Either survival or apoptosis, which is determined by the balance between DNA damage and DNA repair levels, may raise the major problems in cancer therapy.

3. SIGNAL TRANSDUCTION OF P53 AND BRCA1 IN DNA REPAIR PATHWAY

The p53 is inactive under normal physiological conditions and activated in response to various types of cellular stresses including DNA damage, which is also induced and activated in the nucleus by a stress such as hypoxia and oxidative stress. In addition, p53 undergoes post-translational modifications in response to the stresses [21]. The p53 protein is involved in a lot of signaling pathways of cell growth regulation, and multiple mechanisms have been revealed to accomplish the regulation of p53 activity, which determines the selectivity of p53 for specific transcriptional targets, resulting in control of the p53 activity. A number of molecules capable of activating p53 have been developed. Convincing evidence exists for the 53BP1 affecting the outcome of DNA double strand break repair [22, 23]. Among a number of transcriptional targets of the p53, the p21WAF1 has been shown to play an important role in both p53-dependent and independent pathways [24]. The p21 WAF1 inhibits cell cycle progression through interaction with the cyclin and CDK complexes. Studies have shown that p53 is mutated or deleted in nearly half of all human cancers, suggesting that p53 plays a critical role in preventing cancers. During neoplastic progression, the p53 is often mutated and fails to perform its normal functions. The p53 activation by something cellular regulator including a gain of function-mutation may lead to regression of an early neoplastic lesion, and therefore may be important in developing cancer-prevention.

Mutations in the tumor suppressor gene BRCA1 confer an increased risk for the development of breast and ovarian cancers [25]. In particular, BRCA1 hereditary breast cancer is a type of cancer with defects in a DNA repair pathway. Mutation of a single allele of the cancer susceptibility gene BRCA1 is associated with increased genomic instability in human breast epithelial cells [26], which accelerates the mutation rate of other critical genes. Several functions of BRCA1 may contribute to its tumor suppressor activity including roles in the DNA repair. Although BRCA1 gene mutations are rare in sporadic breast and/or ovarian cancers, BRCA1 protein expression is frequently reduced in the sporadic cases. The BRCA1 has the important role in concert with BRCA2, Rad50 and Rad51 [27], in order to activate the checkpoints. For example, BRCA1 is colocalized with Rad51, a DNA recombinase related to the bacterial RecA protein. The BRCA1 protein becomes hyper-phosphorylated after exposure to the DNA damaging agents, and the function of BRCA1 seems to be regulated by the phosphorylation in response to DNA damage. Pharmacological inhibition of poly-ADP-ribose polymerase induces cell death in tumors with mutations in certain DNA repair pathways, when combined with DNA damaging chemotherapies. Then, poly-ADP-ribose polymerase inhibitors have been investigated for the treatment of patients with BRCA 1 mutation, as a strategy to

potentiate the DNA damaging effects of chemotherapy and irradiation [28, 29]. The role of BRCA1 in cell cycle control has been understood by its ability to interact with various cyclins and cyclin-dependent kinases. The BRCA1 activates the CDK inhibitor p21 and the p53 tumor suppressor protein, which regulates several genes that control cell cycle checkpoints.

4. PROTEIN INTERACTION AND FUNCTIONAL INTERPLAY BETWEEN PTEN AND p53

PTEN gene is the frequently mutated and deleted tumor suppressor in human cancer. Human genomic *PTEN* locus consists of nine exons on chromosome 10q23.3, encoding a 5.5 kb mRNA that specifies a 403 amino-acid open reading frame [30, 31] (Figure 2), which is ubiquitously expressed throughout early embryogenesis [32]. The translation product is a 53 kDa protein with homology to tensin and protein tyrosine phosphatases. The PTEN inactivation is implicated in the carcinogenesis of several cancers [33], which causes an increase in cellular PIP3 levels, by which activated PI3K/AKT signaling causes increased expression of several genes for cell survival. PTEN and p53 is known to interact and regulate each other (Figure 1) at the transcription as well as protein level, which could be at the important control machinery for switching between survival and death. This cross talk is frequently a combination of reciprocally antagonistic pathways, which often involves another tumor suppressor gene MDM2. The cross talk may serve as an added regulatory effect on the expression of key genes involved in cancer. It has also been revealed that PTEN regulates p53 stability and in turn regulates its own transcriptional activity. The PTEN and p53 complex enhances p53 DNA binding and transcriptional activity [34]. An important p53 function is to act as a transcription factor by binding to the specific DNA consensus sequence in responsive genes, which may increase the synthesis of p21^{waf1} that is an important protein involved in cell cycle arrest [35]. In addition, one of transcriptional targets of p53 is also the PTEN. One way by which p53 inhibits production of PIP3 indirectly is by inducing the expression of PTEN [36]. The p53 and AKT influence the process of apoptosis in opposite ways. The AKT promotes cell survival by suppressing pro-apoptotic proteins such as Bad through phosphorylation [37]. There are also cross talks between p53 and AKT involving gene transcription as well as posttranslational protein modifications. One way by which p53 inhibits PIP3 production indirectly is by repressing the catalytic subunit of PI3K. A subsequent p53-induced expression of PTEN causes the p53-PTEN interaction, which then suppresses the cell survival machinery of AKT pathway. PTEN is required for the maintenance of p53 acetylation, which is also required for target gene transcription [38].

Growth factor-activated AKT signaling promotes progression of cell cycles by acting on downstream factors involved in controlling the G1/S and/or G2/M transitions. Several studies have also implicated AKT in modulating DNA damage responses and genome stability [39]. AKT therefore modifies downstream signaling in complex ways. In addition, PTEN also plays a critical role in DNA damage repair and DNA damage response through its interaction with p53 pathways in an AKT-independent manner [40]. Furthermore, nuclear PTEN is sufficient to reduce tumor progression in a p53 dependent manner. It has also been suggested that nuclear PTEN play a unique role to protect cells upon oxidative damage and to regulate carcinogenesis [41]. One aspect of the PTEN tumor suppressor signaling is achieved through stabilization of

the p53 protein. PTEN has been shown to physically interact with p53 and prevent its degradation. The instability of PTEN correlated with its missense mutations has been shown to involve protein interactions. PTEN may be regulated by ubiquitin-mediated proteasomal degradation, a common mechanism to control protein levels.

Figure 3. Implication of tumor suppressor gene modulations in cancer. Expression of tumor suppressor genes is regulated by genetic, epigenetic, and transcriptional changes, which may result in the DNA repair activity in a cell. The DNA repair downregulation can contribute to genomic instability, which promotes malignant transformation of cells.

5. PERSPECTIVE

Tumor suppressor molecules protect a cell from cancers. When the tumor suppressor genes lose their function by genetic changes such as mutations or deletions, the cell may progress to cancer in combination with other genetic changes (Figure 3). The phenotype of the cancerous cell may also arise from epigenetic events that may alter the gene expression. Epigenetic silencing of the tumor suppressor genes is a well-established oncogenic process [42]. So, the epigenetic modifications are of particular importance for the imprinted genes which are generally located in clusters [43, 44]. They are differentially marked by DNA methylation, histone acetylation, deacetylation, and histone methylation [45]. However, the molecular mechanisms by which they regulate developmental transitions have not yet been well defined. Epigenetic differences accumulate with age and different environments create different patterns of cellular modifications. Transient nutritional, biophysical, or biochemical stimuli occurring at specific stages may have influences on gene expression by interacting with epigenetic mechanisms and altering chromatin compaction and transcription factor accessibility [46] (Figure 3). Actually, the mRNA and protein expression level of the tumor suppressor genes is increased following treatment with drug, hormone, or food. For example, rosemary extract represses *PTEN* expression in K562 leukemic culture cells [47]. It has been paid more attention

to the DNA repair, because specific cancer prevention may be possible via the mechanisms. The cancer cell genome is aberrant as a consequence of incomplete DNA repair. As many anticancer drugs further reduce the integrity of DNA, they may be able to cause more mutations and another cancer, if the lesions are not repaired. However, cancer cells, in which its DNA repair is down-regulated, have been shown to exhibit increased sensitivity to DNA damaging chemotherapy. Understanding of the cellular aberrations of cancer cells has allowed the development of therapies to target biological pathways. Several studies have evaluated the role of DNA repair enzyme inhibitors for treatment of cancer [48, 49]. Further investigations will be required to identify other additional mechanisms associated with the therapeutic sensitivity. Also, future studies should be conducted to determine whether the combination of DNA damaging agents and DNA repair modulator has potential for the treatment against cancer.

ABSTRACT

Neurofibromatosis type 1 (NF1) is one of the most common inherited neurological disorders. Clinically, NF1 is characterized by café-au-lait spots, skinfold freckling, cutaneous and subcutaneous neurofibroma, plexiform neurofibroma, Lisch nodules, bony defects and frequently by a positive family history in first degree relatives. The causative gene encodes a large protein, neurofibromin, a negative regulator of the RAS signaling pathway. In addition to neurofibromatosis, several other disorders such as Noonan syndrome, Costello syndrome, Legius syndrome and cardio-facio-cutaneous (CFC) syndrome also result from a dysfunctional RAS pathway; therefore, all of these diseases have been grouped as RASopathies. While the molecular genetics of NF1 are well studied, the biological processes underlying the development of NF1-associated pathologies have yet to be fully understood. Using a systems biology approach to integrate various global, molecular profiling data can provide insights into the function and interactions of key regulatory molecules associated with NF1. These include transcription factors and microRNAs. This may ultimately lead to the discovery of new diagnostic markers and the identification of therapeutic targets.

INTRODUCTION

Neurofibromatosis (NF) is the most common hereditary neurological disorder. It was first described by German pathologist Friedrich Daniel von Recklinghausen [1]. Neurofibromatosis type 1 and 2 (NF1 and NF2) are the two major forms of autosomal dominant neuro-cutaneous syndromes. They show no special preference for race and gender. NF1 is caused by mutation(s) of the neurofibromatosis type 1 gene (*NF1*), which encodes a multi-domain protein, neurofibromin. Clinically, NF1 has extremely variable manifestations which include multiple café-au-lait spots (CALS), cutaneous neurofibromas, plexiform neurofibromas, iris hamartomas (Lisch nodules), bony defects and neoplasms of the nervous system. Although tumors in NF1 are usually benign in nature, transformation of plexiform neurofibroma to form malignant peripheral nerve sheath tumors, occurs in approximately 10% of NF1 patients.

EPIDEMIOLOGY OF NF1

In 1981, Samuelsson reported the first population-based prevalence study of NF1 with a prevalence of 1/4600 in the Gothenburg region, Sweden [2]. Huson *et al.* surveyed South East Wales, UK and reported a prevalence of 1/4150 [3]. The highest estimated prevalence of NF1, 1/2190, was reported in 1989 in Dunedin, New Zealand [4]. Several studies with populations from northeast Italy and northern Finland also gave an estimated occurrence rate between 1/2983 and 1/6711 [5]. Accordingly the average prevalence of NF1 has been estimated to be about 1/3500 [6-8] with a birth incidence varying from 1/2558 to 1/4292. There is no evidence of ethnicity differences in the frequency of NF1 based on the results of different prevalence studies [9].

CLINICAL FEATURES OF NF1

For the majority of patients, the diagnosis of NF1 is based exclusively on the clinical features. The NF1 diagnosis requires the presence of at least two of the major clinical criteria: six or more CALS, axillary or inguinal freckling, two or more cutaneous neurofibromas, one plexiform neurofibroma, characteristic bony defects (pseudarthrosis, sphenoid wing hypoplasia, and scoliosis), optic glioma, two or more iris Lisch nodules, or a positive family history with a first-degree relative with NF1 [10]. Most of the clinical features associated with NF1 increase in frequency with age among affected children [3, 6, 11-15]. Many infants and young children who are *NF1* gene mutation carriers do not fulfill the clinical diagnostic criteria for NF1 [3, 14, 16-18], but the disease is apparent in almost all affected individuals by 8 years of age and in all affected individuals by age 20 [11, 14].

CALS, pseudarthrosis, and externally visible plexiform neurofibromas can be identified in early infancy, while freckling, optic gliomas, and severe scoliosis occur by the first decade of life. Upon progression, cutaneous neurofibromas and iris Lisch nodules usually appear in teenage to young adult years in NF1 patients [19]. Therefore, NF1 is a progressive condition with variable complications and may worsen with time.

Skin Manifestations

CALS are well circumscribed, evenly pigmented light to dark brown macules averaging 2–5cm in diameter in adults, but they may vary from 2mm to more than 20cm [20]. The frequency of having more than six CALS, which is considered as a cut-off for the NF1 diagnostic criteria, is rare in normal individuals. The CALS must be at least 0.5 cm in diameter in prepubertal individuals and 1.5 cm in postpubertal patients. In addition to NF1, other syndromes associated with one or multiple CALS include McCune-Albright syndrome, Legius syndrome, Noonan syndrome, other cardio-facial-cutaneous syndromes (RASopathies), and constitutional mismatch repair deficiency syndrome [20]. A significant increase in melanocyte and mast cell density in CALS indicates the possible involvement of mast cells and melanocytes in CALS formation [21].

Even though the etiopathogenesis of these skin macules is still elusive, the local fluctuations of keratinocyte-derived membrane-bound stem cell factor (SCF) and mast cell growth factors (MCF) could be important for the development of CALS [22, 23]. Diffuse freckling is another common clinical phenotype in NF1 and clustering hyperpigmentation on the axilla and inguinal area is very common in NF1 patients. Whether the freckling is also associated with SCF and MCF has yet to be determined.

Neurofibroma, a benign tumor derived from cutaneous or subcutaneous nerve sheath is common among NF1 patients. The tumor is comprised of Schwann cells, fibroblasts, perineural cells, mast cells, nerve axons and blood vessels. Some neurofibromas erupt with a broad base of skin involvement, but others are pedunculated lesions. Neurofibroma may be discrete, homogeneous, and well circumscribed, or diffuse, heterogeneous, and infiltrative (plexiform).

Plexiform neurofibromas account for substantial morbidity associated with NF1, including disfigurement, functional impairment, and can be life threatening. Facial dysmorphisms with visual loss are not uncommon in large facial plexiform neurofibromas [24, 25]. In a retrospective survey, six patients with hemifacial hypertrophy were identified to be caused by plexiform neurofibroma with a delayed diagnosis [26]. Histologically, plexiform neurofibromas are similar to cutaneous neurofibromas, but have more extracellular matrix and blood supply. They can arise from the dorsal spinal roots, nervous plexi, large nerve trunks, or sympathetic chains. Malignant transformation into malignant peripheral nerve sheath tumors (MPNST) occurs in approximately 10% of NF1 patients. The diagnosis is often delayed since these cancers typically arise in pre-existing tumors, i.e., neurofibromas. Surgical resection is the mainstay of treatment, and the adjuvant radiation therapy and/or chemotherapy are not well defined, although adjuvant therapy may be of benefit in some patients [27]. The prognosis of patients with incompletely resected, recurrent or metastatic MPNST is dismal.

Skeletal and Osseous Abnormalities

Abnormal skeletal development occurs in roughly 10–20% of NF1 patients [28, 29]. Skeletal manifestations in NF1 patients include bony dysplasia, bony erosion, demineralizing osteoporosis, non-ossifying fibromas, and scoliosis [30]. The most incapacitating problem is congenital pseudarthroses of long bones.

Five percent of NF1 patients develop pseudarthrosis, usually involving the distal one third of the tibia and fibula [31]. Orthopedic surgery to correct NF1 skeletal defects often fails due to pseudarthrosis [28].

Low bone mass, consistent with osteoporosis, has been reported in both young and adult NF1 patients [32]. Fractures of deformed bones occur in 5–10% of young NF1 children, especially boys [31]. Both the demineralization and non-ossifying fibromas can lead to fracture especially in the femur, tibia, and humerus.

Multiple forms of scoliosis occur in at least 10% of NF1 patients. In our NF1 clinic, 25% (17/68) of the NF1 patients were diagnosed with spinal scoliosis [33]. Images from an NF1 patient with both scoliosis and ankylosing spondylitis are shown in Figure 1, implying both developmental and inflammatory processes are involved in the development of skeletal problems in NF1 patients (Figure 1A and 1B). Rapid progressive abnormal curvature of the spine (kyphoscoliosis) needs to be corrected surgically. Fortunately, juvenile scoliosis is often self-limited.

A mouse model lacking a functional *Nf1* allele develops misalignment between vertebral bodies by 1 month of age, scoliosis by 3 months of age and vertebral fusion with severe loss of bone density by 6 months [34]. Blocking RAS/ERK activation by lovastatin during embryonic development reduces the cortical porosity, which suggests the involvement of neurofibromin in RAS/ERK pathway activation. Therefore, the abnormal activity of RAS/ ERK pathway maybe critical for the vertebral and tibia lesions in NF1 patients, and proteins associated with the RAS/ERK pathway may represent good therapeutic targets for NF1 [34].

Figure 1. Plain X-ray images of the thoracolumbar spine viewing through lateral (A) and anterior-posterior (B). The patient suffered from scoliosis and ankylosing spondylitis, resulting in vertebral fusion (bamboo spine).

Vascular Lesions

The majority of functional defects in NF1 involve neuroectodermal tissues including nervous tissue, skin, skeletal system, tooth and blood vessels. Structural abnormalities such as overgrowth after intimal injury, dysplasia of the vascular smooth muscle layer and adventitia in both large and small vessels can be identified in NF1 patients [35]. Common vascular complications of NF1 include arterial stenosis, aneurysm, and arteriovenous fistulas involving the abdominal aorta and its branches. We have reported a fatal brain ischemia caused by multifocal stenosis in intracranial arteries with complete occlusion of the left middle cerebral artery in a NF1 patient [36]. Recently, Gao *et al.* also reported a case with coexistence of a left renal artery stenosis and aneurysm detected by the color duplex ultrasound [37].

Psychiatric Disorders and Cognitive Dysfunction

As compared to the general population, psychiatric disorders occur more frequently in patients with NF1 (33% of the patients) [38]. The most common psychiatric problem is dysthymia (21%). There is also a high prevalence of depression, anxiety, and personality disorders in NF1 patients. The impaired quality of life (QoL) associated with NF1 might contribute to the development of psychiatric disorders. Using the questionnaire SF-36 and Skindex, Page *et al.* screened 176 American NF1 patients and showed that the more visible NF1 associated skin disfigurement, the greater the impact on the QoL [39].

Learning disabilities and attention deficit have been reported in as many as 60% of NF1 patients, which may lead to poor performance in school [19]. However, the frequency of major cognitive impairment in our cohort is low [33] and most of our NF1 patients' intelligence falls within normal limits.

Rare Manifestations

In addition to the common clinical features associated with NF1, there are also some rare clinical manifestations such as segmental neurofibromatosis (NF type V) which involves only parts of the body. Most segmental neurofibromatosis patients do not have a positive family history and the disorder has been speculated to be derived from postzygotic *NF1* gene mutation(s). The disease is usually confined to one sector of the body and patients may not have other NF1 stigmata, such as axillary freckling, neurofibroma or CALS [40]. Segmental NF does not progress to the common NF1 phenotype and malignancy is also rare among segmental NF1 patients [40].

RASopathies

A few diseases, such as NF1, Noonan, Costello, Legius and cardio-facio-cutaneous (CFC) syndromes share some clinical features including mental subnormalities, facial dysmorphism, cardiomyopathy, short-stature, dysplasia, bony defects, and cutaneous freckling and

pigmentation. All of these disorders result from aberrations in the RAS-MAPK pathway and they have been grouped together as RASopathies. Relative macrocephaly, ventriculomegaly and Chiari malformation can also occur in patients with RASopathy [41]. Dinçer *et al.* reported that 7 out of 54 NF1 patients suffered from hydrocephalus. Although the types of obstruction vary among patients, the presence of hamartomas was a common finding [42]. Figure 2A and 2B show the obstructive hydrocephalus with large ventricles in one of our NF1 patients. An abnormal flap bridges the fourth ventricle between the vermis and area postrema.

Dysplasia and Developmental Defects

Dysplasia is an abnormal growth of a tissue during development or dysregulated wound healing, while neoplasia is an uncontrolled proliferation of cells. Cortical dysplasia with seizure has been reported in some NF1 patients.

Animal models with neurofibromin haploinsufficiency also resulted in abnormal astrocyte proliferation in different brain regions [43]. In some cases, cortical dysplasia is correlated with ganglioglioma and dysembryoplastic neuroepithelial tumors in NF1 patients (Figure 3A and 3B) [44, 45]. NF1 patients also show wide-spread vasculature dysplasia in endothelial cells and pericytes, especially in the brain, gastrointestinal tract and kidney [36] [46-48]. The common clinical symptoms associated with NF1 including short stature, scoliosis, and joint pseudarthrosis are also dysplastic features of osteoblasts.

Even though some neurofibromas in NF1 patients appear to arise from dysplastic responses to injury, a significant number of them are present from birth, suggesting embryonic or fetal growth abnormalities [49].

Figure 2. Sagittal T2WI (A) and axial T1WI (B) MRI images of an NF1 patient demonstrates the prominent enlarged ventricles and an abnormal flap bridge (arrow) in the fourth ventricle between the vermis and area postrema. There is no tonsillar herniation, Chiari malformation, progressive forehead bossing or posterior fossa crowding.

Histopathologically, neurofibroma is different from the proliferation of a single cell type frequently seen in neoplasm. Instead, neurofibromas are a mixture of multiple cell types including Schwann cells, fibroblasts, endothelial cells, pericytes, mast cells, occasionally lymphocytes and perineurial cells with extensive extracellular matrix, intercellular collagen and mucopolysaccharide-rich substances [50, 51].

In an animal model, the grafted plexiform neurofibroma will not grow unless neurofibromin-deficient Schwann cells are explanted with *NF1*^{+/-} mast cells [52]. In addition, a few patients report intense itching during the growth of neurofibroma which may indicate the involvement of mast cells [53]. Based on these findings, an initial trial of imatinib mesylate (a receptor tyrosine kinase and cKit inhibitor for mast cells) on one patient with a large mediastinum plexiform neurofibroma, had positive results [53]. Imatinib mesylate has also shown efficacy in treating plexiform neurofibroma in a xenograft model [54]. Studying the interactions among different cell types in neurofibromas will continue to shed light on the mechanisms of tumor formation and growth [55].

MOLECULAR GENETICS OF NF1

Genetic Diagnosis

The human *NF1* gene has 60 exons and encodes a 12-kb transcript covering 350 kb at chromosome 17q11.2 [56, 57]. Mutations of the *NF1* gene consist of small deletions, small insertions, nonsense and missense mutations, intronic mutations, and deletions of the majority of the *NF1* gene or the entire *NF1* gene. Most of the mutations are minor changes while only approximately 5% are total gene deletions [58]. Many germline mutations result in frameshift or nonsense mutations. The mutation rate at the *NF1* gene is estimated to be $\sim 1 \times 10^{-4}$ /gamete/generation making it one of the most frequently mutated genes in human [3, 8]. Approximately 50% of all mutations arise *de novo* and do not appear to be clustered within the gene.

Mutations in the *NF1* gene have been observed in several different types of malignancies including neurofibroma, glioma, MPNST, non-lymphocytic leukemia, and pheochromocytoma.

To date, 1348 publically available mutations of the *NF1* gene have been collected in The Human Mutation Database (HGMD, <http://www.hgmd.cf.ac.uk/ac/gene.php?gene=NF1>) which may explain, in part, the wide spectrum of clinical presentation of NF1. There are probably additional mutations associated with the *NF1* gene. However, the identification of new mutations is hindered by the absence of mutation hotspots and the size of the gene. For the vast majority of patients, the identification of the specific type of NF1 mutation does not currently aid in prognostication, disease management, or treatment selection.

Several methods are used to screen for *NF1* mutations including single-strand conformational polymorphism (SSCP) [59], denaturing gradient gel electrophoresis [60], denaturing high-performance liquid chromatography [33], protein truncation test [61] and fluorescence *in situ* hybridization [62]. Some of these tests must be combined with DNA sequence analysis to document changes leading to abnormal profiles. Loss of heterozygosity of the flanking and intragenic microsatellite markers and the quantification of *NF1* copy number, have been used in detecting large deletions [33].

Figure 3. Brain MRI (A) and PET (B) images of an NF1 patient with intractable seizure. The patient demonstrates a suspected dysembryoplastic neuroepithelial tumor (DPNT) in the left frontal region (arrow). The ^{18}F -glucose PET images (B) show a high intensity at the tumor site indicating a correlation between the tumor and epilepsy.

Because screening for NF1 mutations is laborious and expensive, a robust, sensitive and cost-effective alternative for the heteroduplex detection or large-scale sequencing would be preferred by genetic laboratories. DNA sequencing-by-hybridization (SBH) was initially proposed by Drmanac and Crkvenjakov [63]. This approach is an indirect sequencing method in which probes designed to read all possible sequences in any DNA sample hybridizing to DNA template molecules.

A further advance of SBH technology is combinatorial SBH (cSBH), which utilizes a DNA ligation step for two short probes, in which one is attached to a solid support (a glass array slide) and the other is free in solution and labeled with a fluorophore. When both array-bound and solution-phase labeled probes hybridize to the target DNA at contiguous complementary positions, they are covalently linked by DNA ligase, creating one long labeled probe attached to the array surface.

The combinatorial process generates all possible probes that are complementary to the target. Using the cSBH method, Schirinz *et al.* screened 30 NF1 patients and identified 25 mutations with high accuracy and readability [64].

Although genetic testing for NF1 has been available since the mid-1990s, technical difficulties in sequencing the entire *NF1* region have prevented it from becoming a routine practice in the clinic [65]. The recent development and maturation of next generation sequencing technology provides a new tool to address the complexity of mutations associated with NF1 [66].

Tumors Associated with NF1

Neurofibromas are comprised of multiple cell types. The most prevalent cell type in the tumor is Schwann cells, which have been proposed to be the tumorigenic cell population [67-69]. In addition to haploinsufficiency resulting from germline mutations in the *NF1* gene, complete inactivation of both copies of the *NF1* gene through additional *de novo* somatic mutations have been reported in NF1 related tumors [70-72]. Based on Schwann cell cultures derived from neurofibromas (38 tumors from 9 NF1 patients), Maertens and his colleagues detected 29 somatic mutations (29/38) in the neurofibromin gene, and the majority of the mutations are small alterations (26/29) of the gene [73, 74]. Only 3 in 29 mutations are loss of heterozygosity (LOH). A similar phenomenon was reported in tumors of patients with von Hippel-Lindau syndrome and in patients with retinoblastoma [75-77]. Given the high occurrence of somatic mutations, reduced DNA repair efficiency could be a trigger in neurofibroma development. The frequent changes in the genome of cancer cells led to the hypothesis of genetic instability as a prerequisite factor for cancer progression. MPNST in NF1 patients usually originates from plexiform neurofibroma. To elucidate the transition, Kobayashi *et al.* karyotyped 10 MPNSTs from nine patients and found more chromosomal aberrations as a consequence of chromosomal instability in MPNST [78]. However, these results must be interpreted with caution due to inadequate detection techniques, the limited number of samples and the mixed cell population that were used in the studies.

Disease Modifier Genes in NF1

The high inter- and intra-familial variability of NF1 symptoms suggests the possible involvement of modifier genes and/or environmental factors in NF1.

Identifying these modifier genes or environmental factors could provide new insights into the underlying mechanism of the disease and offer more effective therapeutic or disease management approaches. Atypical NF1-like symptoms may be the result of mutations in genes other than *NF1* [79], and these mutations may also affect the symptoms and severity of *NF1* gene-associated neurofibromatosis. Clinical statistics show that patients who are homozygous or compound heterozygous with *MSH6* (mutS homolog 6) mutations, a mismatch repair gene, will develop NF1 like symptoms [80, 81]. The expression level of *MSH6* gene also correlates with the number of café-au-lait spots, which is one of the key clinical phenotypes of NF1. In addition to *MSH6*, individuals with *SPRED1* (sprouty-related, EVH1 domain containing 1) mutations also display NF1-like disorders. Easton and his colleague showed monozygotic twins have the highest *NF1* gene genotype and neurofibromatosis phenotype correlation followed by first-degree relatives and more distant relatives. The high degree of correlation between monozygotic twins suggests a strong genetic component in NF1 pathology, but the low correlation between distant relatives suggests additional genetic factors other than the *NF1* locus may play a role in the pathology of neurofibromatosis [82]. The NF-France Network has phenotyped and genotyped 750 NF1 patients and affected relatives from 275 families. NF1-related clinical features, including five quantitative traits including number and size of café-au-lait spots, and number of cutaneous, subcutaneous and plexiform neurofibromas were scored.

Heritability estimates of those quantitative traits ranged only from 0.26 to 0.62 [83] which suggest the contribution of additional genetic factors to the NF1 clinical symptoms.

However, a separate study of 175 NF1 individuals, including six monozygotic twin pairs, showed high degree of concordance in clinical features between twins and first degree relatives [83]. Two additional studies also demonstrated strong phenotype and *NF1* genotype correlation [82, 84]. In addition, patients with deletions in the *NF1* gene exhibit severe phenotypes with early-onset neurofibroma [85]. Upadhyaya and her colleague also demonstrated that NF1 patients from five unrelated multi-generation families having a single amino acid deletion ('AAT' p.990delM) in exon 17 do not developed cutaneous neurofibromas [86]. These studies revealed a strong phenotype-genotype correlation which argues against the existence of symptom-specific modifier genes for NF1. More recently, a study using a Gene-Chip containing over 900K single nucleotide polymorphism to genotype 300 patients with extreme tumor burden failed to identify a single common polymorphism associated with tumor burden [87].

Molecular Pathogenesis of NF1

NF1 is expressed ubiquitously in different tissues and cell types [88, 89]. Results from immunoprecipitation and Western blot analysis suggest neurological tissues and associated cells including neurons, oligodendrocytes, dorsal root ganglia, and nonmyelinating Schwann cells have the highest concentration of neurofibromin. In rat and human skin, neurofibromin is also expressed in keratinocytes and menalocytes [90].

The *NF1* encoded protein, neurofibromin, contains a GTPase activating protein (GAP) family domain [91]. It has been shown that loss of neurofibromin function is associated with increased levels of activated RAS-GTP in malignant Schwann cells, which suggests the involvement of neurofibromin in modulating cellular RAS-GDP and RAS-GTP levels [92, 93]. In addition, neurofibromin degradation is necessary for maximal RAS activation by growth factors, and neurofibromin expression is required to attenuate the RAS-mediated signaling process [94].

Activation of PKC rapidly induces neurofibromin degradation. McGillicuddy *et al.* demonstrated that only the protein kinase C (PKC) inhibitor bisindolylmaleimide I (Bis I), but not the inhibitors of PI3K or MEK, blocked neurofibromin degradation in response to multiple growth factors in NIH 3T3 cells [95]. These results suggest the involvement of neurofibromin in the growth factor receptor-PKC-RAS signal pathway [95] and NF1 associated clinical phenotypes may be the results of aberrant activation of the RAS pathway [92, 96].

Recently, Yang *et al.* demonstrated that transforming growth factor- β (TGF β) secreted by *Nf1*^{+/-} mast cells can increase the proliferation, migration and collagen synthesis of the *Nf1*^{+/-} fibroblasts [97]. This TGF β -induced change in fibroblasts was mediated through RAS-dependent activation of c-abl [97].

The same group further demonstrated the need of proper microenvironment for the growth of neurofibroma from NF1 deficient Schwann cells in a xenograft animal model. After transplanting human *NF1*^{-/-} Schwann cells in bone marrow, the growth of neurofibroma from nerve roots can be identified in the recipient mice with a defective *Nf1* allele in bone marrow [53], while those in the wild type did not develop any neoplasm.

Based on the understanding of the RAS-c-abl and c-Kit signaling pathway, these investigators demonstrated the inhibition of neurofibroma growth in animal model by treating the animal with imatinib mesylate which is an inhibitor for c-Kit tyrosine kinase. Imatinib has

also been successfully tested on a patient with an enlarged plexiform neurofibroma on the neck and mediastinum [53].

Neurofibromin may have additional non-RAS related functions, including regulating intracellular cAMP level [98]. The phenotype associated with *NF1*-deficiency in *Drosophila* can be rescued by over expression of cAMP dependent activated protein kinase A but not by manipulating RAS signaling [99]. Tong *et al.* also showed that the cAMP-related phenotypes of these flies could be rescued by the expression of a human *NF1* transgene [100].

In mouse *Nf1*^{-/-} astrocyte culture, loss of neurofibromin was found to have a positive influence on cAMP generation and activation of cAMP regulatory targets [101]. In yeast, it was shown that the C-terminal to the GAP related domain (GRD) region of the neurofibromin homologue, Ira1 and Ira2 proteins (RasGAP protein), interact with the kelch Gb proteins Gpb1/2 to stabilize the complex leading to unchecked cAMP–protein kinase A signaling. Thus, the destabilization of the kelch protein–neurofibromin complex may facilitate tumor initiation [102].

Dasgupta *et al.*, using a proteomics-based approach, demonstrated that loss of neurofibromin in astrocytes results in hyperactivation of RAS-dependent and phosphatidylinositol 3-kinase (PI3)-dependent rapamycin (mTOR) signaling pathway [103]. In both *Nf1* mutant mouse optic nerve glioma and in human NF1-associated pilocytic astrocytoma tumors, high levels of ribosomal S6 activation were found to be involved in hyperactivation of the mTOR pathways. Inhibition of the mTOR pathway results in the improvement of *Nf1*^{-/-} astrocyte growth *in vitro* [103]. AKT signaling in fibroblasts of the *Nf1* null mouse was found to be aberrantly activated leading to S6 kinase hyper-phosphorylation [104]. Wortmannin, a PI3 kinase inhibitor, blocks inappropriate activation of mTOR, which depends on the RAS/PI3 kinase effector pathway. The primary target for AKT in this pathway is proposed to be tuberlin, and phosphorylation of tuberlin has been shown to inactivate the TSC1/TSC2 complex, which results in subsequent activation of mTOR [105, 106]. Finally, Johansson *et al.* reported that treatment of subcutaneous sporadic MPNST cell xenografts with mTOR inhibitor, RAD001 (Everolimus) significantly delayed tumor growth and decreased vessel permeability within xenografts [107]. The preclinical results support the consideration of RAD001 in treating NF1 associated and sporadic MPNST.

USING SYSTEMS APPROACHES TO STUDY NF1

One of the aims of systems biology is to decipher biological systems at the network level. The systems approach uses global experimental measurements, such as data from the genome, transcriptome, proteome and metabolome, to build testable hypotheses on molecular interactions. Ideally, identifying networks perturbed in diseases will allow us to identify key molecular events underlying the disease, as well as provide new approaches for restoring disease-perturbed networks. We have previously adapted the systems approach to study complex diseases including human interstitial lung diseases, B cell chronic lymphocytic leukemia, chronic obstructive pulmonary disease and a prion disease model [108-111].

In each of these cases, new molecular processes involved in the diseases and key regulatory factors that could provide new therapeutic intervention were identified.

While previous work has elucidated some of the genes likely to be involved in NF1 pathogenesis and has identified some NF1 biomarkers, a thorough systems approach to identify the changes in the molecular networks underlying NF1 remains to be done. The most comprehensive global molecular profiling with NF1 samples to date, including 20 MPNSTs, 37 neurofibroma, 27 Schwannomas, and 13 synovial sarcomas by Subramanian *et al.* revealed inactivation of p53 and down-regulation of miR-34a in most of the MPNST samples [112]. Down-regulation of the tumor suppressor p53 is commonly observed in cancers, and miR-34a has been previously shown to be directly regulated by p53 [113]. Furthermore, after overexpression of miR-34a in the colon cancer cell line HCT116, expression levels of over 1200 genes were changed [113]. However, the potential roles of p53 and miR-34a dysregulation in MPNST remain unclear.

To expand the network of genes possibly affected by the down-regulation of p53 and miR-34a in MPNST, the results of miR-34a overexpression [113] were used to construct a gene network, taking into account gene expression patterns, protein-protein interactions, transcription factor and miRNA regulation [114]. One of the more interesting changes observed from this analysis is the identification of E2F transcription family members that are upregulated after miR-34 overexpression. E2F transcription factors are involved in cell cycle regulation and aberrant expression of E2F transcription factors has previously been reported in other cancers. This suggests the possibility that part of the dysregulation underlying MPNST is caused through changes in E2F transcriptional activity. Regulatory networks such as these can be useful because they can be applied to longitudinal datasets to follow disease progression.

CURRENT TREATMENT AND DISEASE MANAGEMENT

Despite significant effort, there is currently no effective treatment for NF1. The hallmark of the disease, dermal neurofibromas, although benign, can be painful, debilitating, disfiguring, and can grow large enough to encompass an entire body region. In addition to the high tumor burden for some patients, many cannot be surgically removed because of underlying nerve and vascular involvement. Furthermore, lesions frequently regrow after surgical resection.

It has been shown that dysfunction of several signal transduction elements, including the GTPase RAS, the kinase Src, the tumor suppressor p53 and mTOR-AKT are involved in neurofibroma development. Thus, reagents that block or reverse the abnormal activities related to these pathways may have therapeutic potential in NF1 treatment. As RAS pathway activation is an important feature involved in NF1 associated malignancies, several RAS pathway inhibitors are currently at different stages of clinical evaluation.

To date, there are a number of drugs and treatment strategies in various stages of clinical trials (<http://clinicaltrials.gov/ct2/results?term=NF1andpg=1>) (Table 1). A majority of the trials are aimed at patients with plexiform neurofibroma, including pirfenidone, PEG-interferon alpha-2b, imatinib, sirolimus, vinblastine with methotrexate, and photodynamic therapy [115]. Some of these trials are listed below.

Tipifarnib (IR115777): Tipifarnib is an inhibitor for farnesyl transferase, a key enzyme for RAS activation, which transfers a farnesyl group from farnesyl pyrophosphate (FPP) to the pre-Ras protein. A phase 1 clinical trial with tipifarnib including NF1 patients with plexiform

neurofibromas has been conducted by Widemann et al. [116]. A subsequent phase 2 study has been completed, but the results have not yet been published.

Table 1. Summary of clinical trials for NF1 and related conditions registered in US National Institutes of Health (<http://clinicaltrials.gov/ct2/results?term=NF1andpg=1>) and in the recent report from Children's Tumor Foundation Annual Meeting [87]

Condition	NF1	Plexiform neurofibroma	Low-grade glioma associated with NF1	Unresectable meningioma, intracranial hemangioblastoma	MPNST
Agent	Lovastatin	Imatinib Methylete	Tarceva and Rapamycin	Sunitinib Malate	Filgrastim, doxorubicin hydrochloride, etoposide, ifosfamide, conventional surgery, and radiation therapy
	Skincerity plus sirolimus/ rapamycin	Sorafenib	RAD001 (Everolimus)	Bevacizumab	Imatinib Mesylate
	Methyphenidate	Nilotinib	Carboplatin, Vincristine		Bevacizumab and Everolimus
	Pirfenidone	R115777 (Tipifarnib)	Sorafenib		
	Local injection of ranibizumab	Sirolimus	Lenalidomide		
	Imiquimod 5% Cream	Pirfenidone			
	Cediranib maleate	PEG-interferonalpha-2b			
	Erbium-YAG laser vaporization	Cediranib maleate			
	Sorafenib	Peg-Interferon alpha-2b, Celecoxib, Temozolomide, Vincristine			
	Vitamin D3	Mexotrexat, Vincristine			
		LS 11 (Talaporfin sodium)			

Sorafenib: Plexiform neurofibroma may be susceptible to the inhibition of Ras/Raf/mitogen-activated protein kinase (MAPK) pathway.

Thus, sorafenib, an oral receptor tyrosine kinase inhibitor has been evaluated in children with inoperable plexiform neurofibromas and MPNST [115], with publication of the final study results pending.

Sirolimus (Rapamycin): Sirolimus is an antifungal antibiotic. It inhibits cell cycle progression through the inactivation of mTOR kinase and has anti-proliferative effects [117]. Sirolimus is being evaluated for the treatment of plexiform neurofibromas in a phase 2 study.

Cediranib: Cediranib is a small molecule inhibitor of vascular endothelial growth factor receptor (VEGFR) and is being investigated in patients with NF1 and plexiform neurofibromas.

Pirfenidone: Pirfenidone, an inhibitor for TGF synthesis has been tested in adult patients with NF1 in an open label trial published by Babovic-Vuksanovic *et al.* [118]. Four out of 17 patients had a decrease in tumor volume by 15% or more [118].

Imatinib: Imatinib targets c-kit and PDGFR, and has been reported to be effective in tumor reduction in a subset of patients with plexiform neurofibroma. Symptom improvement was also reported in some patients [87].

HMG-CoA reductase inhibitor: Besides treating NF1 associated tumors, approximately 30% to 65% of children with NF1 suffer from a broad range of both nonverbal and verbal learning disabilities [119]. A Phase I trial of Lovastatin for children with NF1 and cognitive deficits was completed and found improvement of specific cognitive areas, such as memory, recall, and recognition [115].

CONCLUSION

Neurofibromatosis type 1 is a complex disorder, with widely variable clinical features. Anticipatory guidance, surveillance, symptom management and surgical and/or medical treatment of NF1-associated tumors are the main therapeutic approaches in the clinic. Current evidences suggest the haploinsufficiency of neurofibromin is the underlying key pathogenic factor for NF1 and its associated dysplasia and neoplasm. Understand how normal molecular network affected by dysfunctional neurofibromin through comprehensive systems biology studies may inform new therapeutic approaches in the future.

ABSTRACT

This chapter describes the radiographic appearance and distribution of plexiform neurofibromas (PNs) in NF1. Although PNs are histologically benign tumors, they are the source of significant morbidity including disfigurement, pain, functional impairment and they can undergo malignant transformation. Identifying targeted agents that slow the growth or decrease the size of PNs is an area of intense research. Volumetric MRI analysis of PNs is helpful in detecting treatment response and progression in these large and complex shaped tumors with greater sensitivity compared to 1-dimensional or 2-dimensional measurements.

INTRODUCTION

Plexiform neurofibromas are benign nerve sheath tumors affecting multiple fascicles and branches of peripheral nerves. They can develop on any segment of the nerve from the nerve root to the nerve endings. The prevalence of PNs is estimated around 25% in NF1 patients [1-3]. There is no sex predilection. Deep internal PNs are common and may not be clinically apparent [4]. In one study whole body MRI of 65 consecutive pediatric NF1 patients identified 37 patients with PN (57%), only 16 of those patients (25%) had symptomatic tumors [5]. Most PNs present at a young age, may be congenital, and have a tendency to increase in size, especially in early childhood [6]. Significant PN growth in adults is unusual. Overall tumor burden does not always correlate with clinical symptoms, but rapidly growing lesions are more

likely to become symptomatic. Complete surgical removal is rarely achievable and regrowth after surgery is common. Multiple medical treatment options are currently tested in clinical trials. The goal of this chapter is to illustrate the heterogeneity and complexity of these tumors.

IMAGING APPEARANCE OF PLEXIFORM NEUROFIBROMAS

On CT images, PNs present as low attenuation masses and appear hypodense relative to muscle. On post contrast CT scans, PNs enhance only faintly. MRI is the preferred imaging modality for the evaluation of PN burden. On the T1-weighted images (Figure 1A), large PNs demonstrate homogeneous low signal intensity, but smaller tumors can be isointense to muscles. On T2-weighted images PNs are hyperintense with signal intensity similar to or slightly higher than fatty tissue [7, 8].

The pulse sequence known as short TI inversion recovery (STIR) accentuates the long T2 value of the tumors while it provides fat suppression of the surrounding tissues. This technique allows clear separation of PNs from the adjacent tissues and therefore it is uniquely suitable for automatic tissue segmentation and volumetric analysis of these tumors. On the post contrast scans, peripheral PNs show a variable degree and often heterogeneous enhancement which depends on size and vascularity (Figure 1C). The extent of nerve overgrowth varies among patients. Mild segmental nerve enlargement can appear as string of beads alongside the normal distribution of the peripheral nerve (Figure 2A). Around larger solitary nodes the normal rim of fat layer is preserved (split fat sign) and the entering and exiting nerve can be seen centrally to the node. Massive overgrowth of a large segment of the nerve imparts a rope-like appearance (Figure 2B).

Figure 1. MRI characteristics of PN. Axial T1-weighted image of the chest (A) shows a homogeneous low signal intensity mass. On T2-weighted fat suppressed images (B) the mass appears multinodular with peripheral hyperintensity and central hypointensity of the nodes (target sign). On T1 post-contrast images (C) gadolinium enhancement is variable.

Figure 2. PN distribution. Coronal whole body STIR MR images demonstrate high PN burden in three patients. Case 1: (A) 14 year-old female diagnosed with NF1 at the age of 2 years when she was noted to have a neurofibroma on her scalp. Widespread nodular enlargement of peripheral nerves can be seen on the MRI. Her total PN volume measured by volumetric MRI is 2268 ml, accounting for 5.8% of her body weight. Case 2: (B) 34 year-old male diagnosed with NF1 when he suffered a sports injury as a high school athlete and found to have massive PN burden along his sciatic nerves and lumbosacral spine. He developed cervical cord compression at age 28 that required extensive decompression surgery. He has developed progressive weakness, requires wheelchair assistance, and suffers from chronic neuropathic pain. His whole body tumor burden is 6931 ml, 8.3% of his body weight. Case 3: (C) 13 year-old male with large paraspinal PN that extends to of the left thigh and diffusely infiltrates the thigh muscles. Note the leg length discrepancy and scoliosis of the lumbosacral spine. His whole body tumor burden is 3304 ml, 11.2% of his body weight.

Multiple tumors originating from adjacent nerve branches can form large conglomerate multinodular masses (Figure 2C). The center of each individual nodule contains densely packed collagen fibers and has lower signal intensity on T2-weighted and STIR images while the periphery of the tumor contains less organized myxoid intracellular matrix and appears hyperintense. The combined effect of the central hypointensity with the peripheral hyperintense region has been described as the target sign, or central dot sign and is a unique feature of PNs (Figure 1B). The target sign can also be appreciated on CT and ultrasound [9]. Most PNs display pronounced vascularity.

Plexiform Neurofibroma Types

On large nerves, the epineurium is preserved and fully encapsulates the tumor (displacing tumor type) (Figure 3A). Neurofibromas arising from smaller nerves are locally invasive and extend into the surrounding tissues (infiltrative tumor type) (Figure 3B-E).

Figure 3. PN types. Imaging characteristics and variety of PN types on axial STIR MR images of the upper neck in 6 different patients. Panel A shows a fully encapsulated displacing multi-lobular tumor. The larger nodes appear heterogeneously hyperintense while the smaller nodes display the characteristic target sign. On panel B the nerve involvement is more peripheral, the nodes are smaller and interlock with the surrounding muscles. The bright signal in the overlaying skin indicates diffuse infiltration of the skin. The PN shown on panel C appears coarsely granular and infiltrative, involving mostly the muscle layer. On panel D a similar tumor is seen invading the skin, subcutaneous fat as well as facial muscles. Panel E shows a PN with a superficial and a highly vascular deep component. Panel F shows a diffuse superficial PN.

Superficial PNs are diffuse, infiltrative tumors involving the upper layers of skin or subcutaneous fat layer (Figure 3F) [7]. Some patients have a predilection for displacing or infiltrative tumor types, while others exhibit mixed features.

Volumetric Analysis

The size of PNs can range from small to very large, span a few centimeters or the full height of the patient. Most PNs have irregular, complex shape and assessing change over time with line measurements used in the response evaluation of solid malignant tumors is challenging [10-12]. Volumetric MRI analysis allows to sensitively and reproducibly determine small changes in PN size that would be impossible to quantify with conventional response criteria. There is a concerted effort (REiNS, Response Evaluation in Neurofibromatosis and Schwannomatosis) to standardize response criteria on clinical trials for NF1 and other related disorders.

Figure 4. Volumetric MRI analysis of PNs. An outline is generated for every MRI slice that shows PN. The area within the border multiplied by the slice thickness gives the PN volume.

One of the recommendations from the REiNS group is the implementation of volumetric MRI analysis to measure PN size. Different tumor segmentation programs are now available [13-15]. Response evaluation on most clinical trials for PN to date is based on a semi-automatic lesion detection method developed on the MEDx platform [15]. On STIR MR images the bright tumor is separated from the surrounding normal tissue based on signal intensity histogram analysis. The resulting outline is projected over the original image for review (Figure 4). This method has been validated and used successfully in prior and ongoing clinical trials for PNs [16, 17] and also to study the growth behavior and natural history of these tumors [6]. Even with sensitive measurement methods size change is rarely detected within a few months and imaging intervals on clinical trials can be as long as 3-6 months, particularly when the goal of the trial is to increase time to disease progression.

Cranial Nerves

Among the cranial nerves PNs most often affect the trigeminal, glossopharyngeal and vagal nerves. Tumors of the trigeminal nerve can originate from the main trunk in the prepontine cistern or from one of its three branches within the cavernous sinus often causing expansion of this sinus (Figure 5A-B). Unlike other space occupying processes of the cavernous sinus, the slow growing PNs rarely result in overt symptoms. Tumors of the V1 branch can enter the orbit through the superior orbital fissure, leading to the remodeling of the bony structure. Intraorbital PNs of the V1 branch can compress the optic nerve resulting in visual loss. They also commonly produce proptosis of the globe (Figure 5C-D). Sphenoid wing dysplasia can be present with or without PN. Neurofibromas originating from the V2 or V3 branch of the trigeminal nerve may extend into the pterygopalatine fossa or into the soft tissues of the nasopharynx.

The V2 and V3 peripheral branches give rise to tumors in the maxillary or mandibular region. They often involve the tongue, gums and salivary glands. Facial PNs originating from the trigeminal nerve are almost always diffuse, highly invasive and prominently vascular.

Figure 5. Cranial nerve PNs. Case 4: (A, B) 7 year-old female. At birth protuberance of the left eye was noted leading to the diagnosis of NF1 and orbital PN. Her left face became increasingly disfigured. She underwent a partial resection of the tumor at age 5. She has no vision in her left eye and complains of frequent headaches. Coronal (A) and axial (B) STIR MR images through the orbit show a nodular, invasive PN in the inferior aspect of the orbit and facial muscles. Note the marked expansion of the cavernous sinus (arrow). Total volume of the mass is 162 ml. Case 5: (C, D) 13 year-old male with family history of NF1. At birth only a slight fullness around the left eye was noted, but soon the size of his orbital PN increased and he underwent multiple debulking surgeries by age 3. In addition to the orbital lesion he has asymptomatic deep abdominal and paraspinal PNs. His total tumor burden at age 3 was 269 ml that increased to 800 ml currently, about 29% increase in volume per year. MRI shows a diffuse infiltrative PN of the orbit and deep structures of the face with nodular components in the temporal area. The associated sphenoid wing dysplasia is better appreciated on CT (not shown). Case 6: (E, F) 8 year-old female, diagnosed with NF1 at 15 months of age based on skin findings. Right facial swelling was noted at 18 months. Her PN is confined within the parotid gland. The tumor is associated with mandibular remodeling, temporo-mandibular joint asymmetry, malposition of the lower molars, an open bite and asymmetric smile. She has mild conductive low-frequency hearing loss in the right ear due to narrowing of the external auditory canal. Although the tumor is relatively small, 42 ml, it profoundly impacts her quality of life.

They are often associated with varying degrees of cosmetic deformity and functional impairment. Neurofibromas of the facial nerve are rare; some arise within the petrous bone or the facial canal. PNs of the intracanalicular segment can compress the eighth nerve and clinically present with hearing loss or dizziness. When the origin is at the geniculate ganglion PNs cause bone destruction and project into the middle cranial fossa as an extraaxial mass. Neurofibromas of cranial nerve VII have also been described within the parotid gland (Figure 5E-F) arising from the parotid plexus [18]. Facial nerve injury and paralysis most often develops secondary to surgical procedures. The 9th and 10th nerve can give rise to periauricular, retropharyngeal, occipital and neck masses.

Spinal Nerves

Neurofibromas of the spinal canal can be intradural, extradural or both. The intradural tumors are most often found in the cervical and in the lumbar canal. These tumors are best shown on post contrast T1-weighted scans where they show intense enhancement. The intradural tumors, spinal cord and cerebrospinal fluid are also well visualized using Balanced Fast Field Echo (BFFE) technique (Figure 8). They are rounded or fusiform in configuration and, depending on their size, and deform or compress the spinal cord (Figure 6A–C).

Figure 6. Spinal neurofibromas. Case 7: (A, B, C) 40 year-old female with long-standing history of NF1 who presented with right-sided shoulder pain. Coronal (A), axial STIR (B) and sagittal T2-weighted images (C) of the cervical spine show an intradural neurofibroma on the right at C5/6 level that occupies more than 50% of the canal and displaces the cord to the left. Additional smaller intraforaminal neurofibromas and scattered subcutaneous neurofibromas are also present. Case 8: (D, E, F) 15 year-old male diagnosed with NF1 at a young age. His spinal neurofibromas first manifested at the age of 13 years. The MRI shows large bilateral dumbbell lesions at virtually every nerve root with severe cord compression at C2-5 level resulting in pancake like flattening of the spinal cord. After repeated decompression surgeries he developed swan-neck deformity. Now at age 22 he has limited mobility of the neck, but otherwise good performance status. Case 9: (G, H, I) 5 year-old male diagnosed with NF1 at 6 weeks of age based on multiple cafe-au-lait macules. Increase in the circumference of the left upper arm was first noted at age 1. An MRI obtained at that time showed a large left brachial plexus PN with extension into the left hemithorax. Between age 3 and 5 his PN volume increased more than 3-fold from 498 ml to 1513 ml. The MRI shows a large nodular, fascicular PN extending to the upper arm.

Figure 7. Spine deformities associated with PNs. Case 10: (A) 9 year-old male with multiple paraspinal neurofibromas. Enlargement of the neural foramina is seen on the sagittal T2-weighted MR image of the spine at T2-T6 level. Case 11: (B) 4 year-old male with dural ectasia and scalloping of the thoracic and lumbar vertebrae. Case 12: (C) 5 year-old male with large neck PN and history of cord compression. He developed swan neck deformity after multiple laminectomies.

Figure 8. Evaluation of spinal neurofibromas. On axial T2-weighted MR image of the cervical spine (A) the relationship between the spinal cord and C5/6 nerve root is obscured by cerebrospinal fluid (CSF) flow-related signal loss. Balanced Fast Field Echo (BFFE) sequence (B) shows clear definition of the CSF space, spinal cord and extradural neurofibroma on the left side.

Mild spinal cord compression by small tumors can be asymptomatic, while large tumors often produce myelopathy requiring surgical intervention. Extradural tumors are usually located within the neural foramina and often project into the spinal canal causing variable degree of spinal canal stenosis. They are best evaluated by post contrast T1-weighted technique with or without fat suppression. Since they are slowly growing, these tumors tend to gradually erode the bone and produce enlargement of the neural foramina (Figure 7A) and scalloping of the adjacent vertebral body (Figure 7B). Because of the tight confines of the neural foramina, neurofibromas in this location typically assume a dumbbell shape. Spinal cord compression can also occur by extradural tumors, particularly when they happen to be in two neural foramina at the same level and have acquired significant size to project within the spinal canal on both sides (Figure 6D-F). Compression of the spinal cord, either by intradural or extradural tumors, is often accompanied by abnormal signal changes within the cord parenchyma as a result of edema. Cord signal changes that are secondary to edema are reversible after surgical resection

of the tumor and decompression of the cord. Chronic edema however usually leads to alteration of myelin, resulting in myelomalacia that is not reversible and clinically presents with chronic myelopathy. Careful serial neurological evaluation is particularly important in patients with spinal cord compression since development of neurologic deficits can occur with minimal or absent visible changes on imaging studies and may require prompt surgical intervention. Tumor regrowth after surgery occurs frequently and may require multiple revisions. Extensive laminectomies carry the risk of spinal instability that is compounded by NF1 related primary bony dysplasia and manifests as progressive scoliosis, kyphoscoliosis or in most severe form swan-neck deformity of the cervical spine (Figure 7C). Many patients require spine stabilization with metal implants. With current imaging technology, metal artifacts from those implants make radiological evaluation of the spine challenging. The use of titanium reduces this artifact. Enlargement of spinal nerve roots beyond the neural foramina can present as round solitary, fusiform or multilobular masses in the paraspinal soft tissues. In some cases, tumors of the brachial and lumbosacral plexus form giant masses that extend to the extremity and may cause overgrowth of the affected limb (Figure 6G–I). The neurofibromas in the paraspinal regions are best evaluated by STIR MRI technique.

Neck, Mediastinum, Chest

Paraspinal neurofibromas in the thoracic area tend to be less bulky than cervical and lumbosacral tumors, they are most often displacing although invasion into the paraspinal muscles can occur (unpublished observation).

Figure 9. Neck and chest PNs. Case 13: (A, B) 15 year-old male, diagnosed with NF1 at age 10, based on skin findings including subcutaneous neurofibromas. The peripheral nerves throughout his body are enlarged; his whole body tumor burden is 4630 ml, 7.9% of his body weight. The coronal and axial MR images of the chest highlight the thickening of intercostal nerves. Case 14: (C, D) 10 year-old female, diagnosed with NF1 at 18 months of age. A large PN is seen along the descending aorta in the mediastinum and abdomen. She has severe scoliosis and chest deformity resulting in restrictive lung disease. Her brachial plexus PN causes pain in the left axilla and arm. The volume of her tumor is 1175 ml, increased from 263 ml at age 4, at a rate of 75% per year. Case 15: (E, F) 3 year-old male with neck and chest PN and severe airway compression requiring tracheostomy.

Tumors growing along the intercostal nerves (Figure 9A,B) can erode the lower edge of the ribs (ribbon ribs). Mediastinal tumors originate from the vagal nerve or the sympathetic chain (Figure 9C,D). They can be extreme in size, are mostly diffuse, and may cause airway compromise (Figure 9E,F, 10A,B) or swallowing difficulties.

Abdomen, Pelvis

PNs of the autonomic plexus are mostly retroperitoneal [19], some may extend into the mesentery alongside the mesenteric vessels (Figure 11A,B) or more rarely into the liver through the portal system (Figure 11C,D). Bowel obstruction is a rare, but serious complication. Diffuse pelvic tumors can invade the muscle layer of the bladder and cause urinary obstruction (Figure 11E,F) in particular at the vesicoureteric junction. The dense neural network of the uterine wall or the soft tissues of perineum can also give rise to PNs in that area. Tumors of the lumbosacral plexus can be unilateral (Figure 12A,B) or bilateral (Figure 12C,D), and may cause erosive changes to the spine. The concurrent scoliosis can be severe. PN expansion into the paraspinal, iliopsoas, abdominal wall and gluteal musculature is common (Figure 12E,F). Involvement of the sciatic nerve is more frequent than the femoral nerve.

Malignant Peripheral Nerve Sheath Tumors (MPNSTs)

Malignant peripheral nerve sheath tumors are aggressive soft tissue sarcomas with poor prognosis. Rarely seen in the general population, about half the cases are diagnosed in patients with NF1. The lifetime risk of MPNST in NF1 is 8-13% (20, 21). That risk is further elevated if the patient received radiation therapy for optic glioma or other malignancy. The 5-year survival with combination therapy is 21-52% and appears to be worse for individuals with NF1 associated versus sporadic MPNSTs [20, 22-24].

Figure 10. Tracheomalacia. Case 16: 16 year-old male with severe tracheomalacia as a result of a large neck and chest PN. CT of the chest during inspiration (A) shows mild narrowing of the airway (cross-sectional area 1.2 cm²). In expiration phase (B) the narrowing becomes severe (0.2 cm²). He underwent a Y stent placement in the distal trachea that temporarily relieved the symptoms of respiratory distress. He died of probable cardiac arrest a year later.

Figure 11. Abdomino-pelvic PNs of the autonomous nervous system. Case 17: (A, B) 8 year-old female. Multiple areas of skin hyperpigmentation were noted at birth; on the right chest wall one large patch of the hyperpigmentation was associated with roughening of the skin indicating a superficial PN. In addition to the PN in the paraspinal muscles and subcutaneous tissues of the back she also has a large retroperitoneal lesion originating from the sympathetic chain. The PN encases the descending aorta, celiac artery, superior mesenteric artery and renal arteries. Case 18: (C, D) 10 year-old female with family history of NF1. She complains of intermittent abdominal pain since age five; her height and weight are around the 10th percentile. The MRI reveals a PN around the porta hepatis and expanding along the biliary system. The size of the PN has not changed significantly within the past 5 years and she maintains normal liver function. Case 19: (E, F) 3 year-old female, multiple café-au-lait macules were noted at birth raising the suspicion of NF1. The large pelvic PN was discovered at age 1 confirming the NF1 diagnosis. The PN surrounds the bowels and invades the bladder wall causing urinary obstruction. She subsequently underwent ureterostomy and the hydronephrosis resolved. Additional neurofibromas fill the lumbosacral thecal sac, expand the spinal canal, the sacral neuroforamina and infiltrate the gluteal muscles. Between age 3 and 8 the volume of her PNs increased from 808 ml to 3685 ml, more than 90% volume change per year.

In the setting of NF1, most MPNSTs (65-88%) arise in preexisting PNs [20, 25-27] and can be large, invasive or metastatic at diagnosis [22]. Patients with high PN burden may be at higher risk for MPNST [28, 29]. The goal of surveillance is early detection with the hope of curative surgery, which requires complete resection of the MPNST. The most predictable clinical sign of malignant degeneration is new or increasing pain.

The pain can present locally at the site of disease, radiate along the affected nerve or project distally from the lesion. The imaging field should be selected to include the entire nerve from the site of pain to the matching nerve root. Numbness, paresthesia, weakness, other functional deficits, change in consistency on palpation or swelling are also common. Change in size, especially if it is focal and out of proportion to the rest of the PN is concerning. Volumetric MRI analysis allows to accurately establish the tumor growth rate and detect accelerating growth sooner compared to line measurements.

Figure 12. Lumbosacral PNs. Case 20: (A, B) 6 year-old male with family history of NF1. The coronal (A) and axial (B) STIR MR images demonstrate a right-sided lumbosacral and pelvic PN. His tumor first became symptomatic at age 3. He started to turn the right leg outward and his ankle collapsed. Currently he walks with a lower leg brace and requires regular pain medication. Case 21: (C, D) 11 year-old male diagnosed with NF1 in early infancy. By age 5 he was complaining of pain in his legs when walking. His current symptoms include lower extremity weakness that prevents him from bending the knees and severe radiating pain in the back of the legs that he rates 8 out of 10. The MRI shows bilateral paraspinal and deep pelvic PNs. Case 22: (E, F) 7 year-old male with extreme tumor burden; the 5629 ml PN accounts for more than 25% of his body weight. The muscles are atrophied on both lower extremities and he is unable to walk. The bulky gluteal mass makes sitting in the wheelchair uncomfortable and the family is considering amputation.

Other imaging signs that indicate malignant transformation (Figure 13) include changes in the characteristics in some part of the PN, such as disappearance of the target sign, inhomogeneity, patchy contrast enhancement, intra-tumor hemorrhage, necrosis or edema.

None of these signs are specific enough to reliably separate MPNST from a PN. The usefulness of ^{18}F -fluorodeoxyglucose positron emission tomography (FDG-PET) in the detection of MPNSTs has been extensively studied [30-32]. Maximum FDG uptake in benign neurofibromas is generally below 2.0 g/mL, while high grade MPNSTs demonstrate FDG uptake consistently above 3.5 g/mL. However above-background focal uptake can be present in histologically confirmed benign neurofibromas. Therefore, selecting a single diagnostic cut-off that is unequivocal for MPNST is not possible [33]. Diagnostic specificity may be increased with delayed imaging, performed 4 hours after FDG injection. Further increase in uptake on delayed imaging is suggestive of a malignant lesion [32]. FDG-PET is a helpful tool to identify concerning areas in a patient with high PN burden and can be used as a guide to targeted biopsy (Figure 14). Benign lesions with increased FDG uptake, especially those that show cellular atypia, should be closely monitored. There is evidence that atypical neurofibromas harbor chromosomal aberrations reminiscent of MPNST and therefore can be considered premalignant tumors [34].

Figure 13. MPNST. Case 23: (A, B, C) 15 year-old male, diagnosed with NF1 and a neck PN at age 7. Axial (A) and coronal (B) STIR MR images show a right brachial plexus tumor, with nodules displaying the characteristic target sign at the periphery and a distinct homogeneous area in the center. The area where the target sign is lost (arrow) corresponds to high grade MPNST within the PN. The tumor was unresectable at diagnosis. Despite intensive chemotherapy the patient had rapid progression (C) and died of the disease 14 months after diagnosis. Case 24: (D, E, F) 15 year-old male, with long standing history of NF1 and large PN burden. He complained of a fast growing painful node in his right buttock. The fat suppressed T1 post contrast MR image (D) shows avid enhancement at the periphery of the nodule (arrow). On STIR sequence (E) the lesion shows inhomogeneous bright signal and there is edema in the surrounding tissues. Biopsy confirmed a low grade MPNST; the lesion was resected with negative margins. One year after surgery there was no sign of recurrence (F), and four years after diagnosis the patient is alive with no evidence of malignancy. Case 25: (G, H, I) 20 year-old male, diagnosed with NF1 in infancy. Persistent lower back pain prompted the MRI that revealed multiple dumbbell lesions and an 8 cm left paraspinal mass eroding the L1 vertebral body (arrow). On T1 post contrast images (G) his tumors show avid enhancement with some inhomogeneity within the larger node. On T2-weighted images (H) the large node displays variable high signal intensity. CT of the spine demonstrates bony erosion without sclerotic rim (I) suggestive of a fast growing tumor. Histology of the completely resected lesion was consistent with low grade MPNST. Four years after surgery the patient is alive with no evidence of malignancy.

Surgical removal of these lesions should be considered, if feasible without untoward morbidity. FDG-PET may also have a role in detecting treatment response and as a prognostic tool for long-term survival in NF1 patients with MPNST [35]. It remains to be seen whether

alternative PET tracers, for example ^{18}F -fluoro-L-thymidine (FLT) that localizes to sites of high cell proliferation, better differentiate benign from malignant nerve sheath tumors.

Figure 14. FDG-PET imaging. Case 26: 24 year old female with family history of NF1 and large PN burden involving all the major nerves (A). At age 14 she developed a low grade MPNST in the right calf, underwent surgical resection of the tumor followed by radiotherapy. 4 years later she was found to have a high grade MPNST in the right sacral/ischial area; after complete resection she received adjuvant chemotherapy and radiation. She is at high risk of recurrence and is closely followed by MRI and *yearly* PET scans. The FDG uptake in the majority of her benign tumors is similar to background, however several areas of increased uptake are noted (C), SUV 1.9 g/mL in right thigh, 4.0 g/mL in right iliac fossa, 3.6 g/mL in left flank, corresponding to circumscribed nodules within the PNs (B). The size, imaging appearance and PET avidity of these lesions has been stable in the past 6 years.

CONCLUSION

PNs are the second most frequently diagnosed NF1-associated tumors after dermal neurofibromas. PNs involve multiple nerve branches, tend to be large, and often have a complex shape. PNs are best imaged by MRI. On STIR sequences the clear separation of high signal intensity tumor from the surrounding low signal intensity normal tissue allows for automatic tissue segmentation and volume measurement. Volumetric analysis helps to assess the overall tumor burden that can range from a few milliliters to several liters. In one of the above examples PNs account for 25% of the patient's body weight. Over time volumetric analysis can detect small incremental changes in PN size. Fast growing PNs can as much as double in volume within a year; typically PNs grow more slowly or remain stable for prolonged time periods. Other than young age we do not know what influences PN growth rates. Growth behavior may

depend on tumor type, location, size, vascularity, genetic background, hormone levels or environmental exposures. We hope to get better insight about these factors through our ongoing longitudinal natural history study. The extent of PN involvement often can't be predicted from clinical exam. Screening for asymptomatic internal PNs is not recommended at this time due to the lack of effective treatment options. Recently published clinical trials show promise of identifying active medical treatments for PNs. Some of these therapies appear to be more effective in slowing the tumor growth rather than shrinking the tumors and therefore could be tested as preventive interventions before symptoms appear. The recommendation for screening may be reconsidered if prevention of PN growth proves to be feasible and safe. PNs have a high risk for malignant transformation and there is a need to develop better diagnostic tools for the early detection of MPNSTs.

ABSTRACT

Neurofibromatosis Type 1 (NF1) is an autosomal dominant systemic disease. Up to fifty percent of patients with NF1 are reported to have concomitant vascular abnormalities, incidence which increases the mortality especially in young patients. Among the complications of giant neurofibromas, spontaneous rupture and massive hemorrhage has been reported, leading to limb loss and death as well. The resection of larger neurofibromas is a challenging procedure because the risk of uncontrolled hemorrhage is much higher. In this chapter, we present a review of the medical literature of the methods that have been used to control intraoperative bleeding in large neurofibromas. We also discuss a novel surgical technique, which includes the ligation of the base of the giant neurofibroma tissue using a continuous loop-shaped suture. This method makes the operation field relatively bloodless and facilitates identification and ligation of the intralesional vessels. In addition, this surgical technique is less complicated and easier to perform and compared to others.

INTRODUCTION

Neurofibromatosis type 1 (NF1) is an autosomal dominant disorder with an incidence of approximately one in 3,000 live births [1]. The gene locus of NF1 is localized to chromosome 17. Patients with this disorder develop Schwann cell tumors, called neurofibromas, and skin abnormalities. The most characteristic features are the “café-au-lait” pigmented skin spots, Lisch nodules (iris hamartomas), and multiple neurofibromas, including cutaneous and plexiform neurofibromas [2].

In NF1 patients, transformation to a malignant peripheral nerve sheath tumor (MPNST) should be suspected if there is progressive enlargement and pain related to a neurofibroma. If this occurs, surgical excision is absolutely indicated, and also yields the best cosmetic results. Even though hemorrhage following trauma is a rare complication of neurofibromatosis, vascular abnormalities have been found in almost half of neurofibromatosis patients [3]. Macroscopically, these can be vascular stenosis, aneurysms, and arteriovenous fistulae. Microscopically, the most vulnerable are the small and the medium-sized vessels, in which the intima becomes thicker and the media thinner and fibrotic. Abnormal vascular structures are also observed in the neurofibromatous tissue. There are thin-walled, ecstatic blood vessels lying in a loose neural stroma, which replace the normal adipose tissue. For this reason, the risk for severe bleeding during the surgical excision is high, especially in giant neurofibromas [4].

This chapter presents a review in medical literature about the reconstruction options, as well as novel methods to control intraoperative bleeding. Using these methods, the authors present their personal experience in reconstructive surgery of giant neurofibromas and their novel techniques to reduce intraoperative bleeding.

SURGICAL TECHNIQUES

From 2004 to 2012, 16 patients (10 men and 6 women) with giant neurofibromas were operated on in our department. The mean age of the patient was 34 year old. The location of the giant neurofibroma was in the upper limb in 6 patients, in the head and neck region in 5 patients, in the lower limb in 3 patients, and in the chest wall and back in 2 patients. In two patients, one with neurofibroma in the face and the other with it in the left upper limb, the neurofibroma was associated with AVM malformation.

In 12 patients, the neurofibroma was excised and primary closure of the surgical wound was achieved. In the remaining patients, grafting of the surgical skin defect was required. In one patient with neurofibroma in the upper limb, the ulnar nerve was affected and a segment of the nerve was sacrificed. In order to reconstruct the nerve defect, a sural nerve graft was obtained from the right leg and was used to bridge the defect between the ulnar nerve proximally to the common digital nerve of the 4th and 5th digits distally. Another patient with neurofibroma of the upper limb required functional reconstruction of the hand after surgical excision. In this case the extensor carpi radialis longus and radiobrachialis tendon were transferred from the ulnar site to the first metacarpal head, in order to restore the normal function of the hand. In patients with head and neck region involvement, all of the tumors were excised successfully and primary closure of the surgical defect could be obtained. Increased attention should be given to the branches of the facial nerve because of this particular region. In all cases the operations were started with the identification of the marginal mandibular branch of the facial nerve, which crosses the facial artery. Then, working from distal to proximal, the dissection was advanced to the main trunk of the facial nerve as well as to the rest of the branches. In all patients, a total parotidectomy was performed as the tumor extended into the parotid gland (Figures 1–10).

Figure 7. Postoperative photo after the first operation.

Figure 8. A 38 year-old woman with giant neurofibroma of the left upper limb.

A novel technique for prevention of the intraoperative bleeding was used by the authors [5] on a 46-year-old female patient with giant neurofibromas in the bilateral hip region. In the past, the patient had had three surgical excisions of subcutaneous nodules in different anatomical regions for cosmetic purposes, but never in the gluteal region because of the high tendency of intraoperative bleeding. The operation was performed under general anesthesia with the patient in prone position and the hips bent about 15 degrees. After performing the elliptical resection margin, the tumor base was tightened by use of a continuous loop shaped suture ligation. The thread was woven up and down in a loop shaped pattern, with a space of 2 cm between each loop, using a straight needle and prolene 2-0. After skin incision, the dissection was obliquely carried out toward the central and inferior sides of the mass using Metzenbaum scissors, while entering into large vascular sinuses was avoided. The tumor was resected in a wedge shape. The small vessels, which were visualized during the dissection, were

coagulated, and the small bleeding sites were also controlled with the electrocautery. After the skin closure, the loop-shaped ligation of the base was removed, and compressive dressing was performed with gauzes and elastic bandages. The size of the resected tumor was 26x31x21 cm and 24x30x19 cm on the left and right sides, respectively. Due to moderate blood loss, the patient was transfused with two units of packed red blood cells after the operation. The pressure dressing was maintained until the 7th post-operative day. The sciatic nerve was also evaluated during this period, with no evidence of nerve damage. The postoperative period was uneventful with no sign of infection, bleeding, or hematoma. The sutures were removed on the 13th postoperative day, and the patient was discharged the next day (Figure 11–14).

Figure 9. The excised tumor of the left upper limb.

Figure 10. Postoperative photo after total excision of the giant neurofibroma and coverage of the defect with split-thickness skin graft.

In medical literature there are few reports of successful surgical treatment of giant neurofibromas. The high incidence of postoperative complications, the necessity for preserving vital structures such as nerves in head and neck area, and at the same time the importance if the achievement good cosmetics result make the surgical treatment quite challenging. The surgical excision of giant neurofibromas and coverage of the defect using surrounding tissue remains the most popular technique. However, special considerations should be given to the control of intraoperative bleeding and the management of postoperative complications.

Ross [6] presented their experience with the management of a giant 49-kg neurofibroma of the lower extremity in a 37-year-old male with NF1 associated with right thigh pain, paresthesias, increasing edema, and accelerated growth of the mass. In this case the tumor was excised using electrocautery, and hemostasis was maintained with bipolar cautery, ligature and clips. Intraoperative EMG stimulation was used to avoid further nerve injury. An 18-cm rectangular fasciocutaneous flap along the medial proximal thigh was created to cover the defect. The estimated blood loss was 800ml, and the patient received two units of packed-red blood cells. During the following months, the patient was admitted to the hospital three times due to fever, signs of infection and poor wound healing. However, after the appropriate management no further problems occurred, and at the one year follow-up the wound had successfully healed with some residual lymphedema.

Liu et al. [7] reported a 13-year old girl with a large neurofibroma on the back extending into the midaxillary line and measuring 42x48x5cm³. The MRI revealed a diffuse neurofibroma with associated dysplastic blood vessels exhibiting irregular areas of tunica media and sinusoidal-like vascular channels (pseudohemangioma). An angiography demonstrated that the blood vessels of the tumor originated from the intercostal arteries and the transverse cervical artery. Interventional radiologists were unable to embolize such complex vasculature. The neurofibroma tissue was dissected and elevated above the deep muscle fascia, and a large split-thickness skin graft was harvested from the resected tumor tissue in order to cover the entire back.

Less frequently, large neurofibroma can be developed in genitalia. Sadeghi et al. [8] reported a case of giant neurofibroma of the labia major, associated with pain and bleeding from an ulcer on its lateral surface. The size of the tumor was 16 cm in length and 2 to 3 cm in thickness.

Special consideration should be given to head and neck giant neurofibromas. Cheng et al [9] reported a 45-year-old man with a giant tumor in the head, face, and neck. Facial asymmetry was found at birth and became more and more serious with aging. Subsequently, the tumor gradually extended to the head, face and neck and resulted in obvious deformity. This giant tumor was 50 cm in length and 44 cm in perimeter and led to a dislocated and deformed earlap and a longer external auditory channel. The tumor was resected successfully and eyelid anaplasty was performed.

However, apart from the surgical excision of the giant neurofibroma, a novel approach has been presented by Hamdoon et al. [10] using photodynamic therapy in a patient with giant solitary neurofibroma. Their report describes a 70-year old female with painful neck mass associated with slight shortness of breath and dysphagia. Examination revealed a large mass in the neck with no vascular compromise. A core biopsy was performed and histopathological examination revealed a disorganized array of peripheral nerve fascicles. The patient elected to receive photodynamic therapy as the primary intervention. The photosensitizing agent was mTHPC (0,15mg.KG), which was undertaken under general anaesthesia. Post-PDP follow-up

showed that the patient's pain, dysphagia and shortness of breath issues had improved. The disfigurement of the neck caused by the mass was no longer a problem. Three months post-PDT, MRI revealed a significant reduction in the neurofibroma size.

DISCUSSION

Neurofibromatosis type I (NF-1), or von Recklinghausen disease, is an autosomal dominant disorder affecting approximately 1 in 3000 individuals [4]. Typically the disease is diagnosed clinically during childhood, as the first sign in 80% of NF1 individuals is usually café-au-lait macules by 1 year of age. NF1 is a progressive and unpredictable disease that is associated with a variety of clinical outcomes and complications; prognosis is dependent on age, severity of the disease, and organ involvement by the growth of neurofibromas. The life expectancy of individuals with neurofibromatosis may be reduced by 10 to 15 years, most often as a result of malignancies such as peripheral nerve sheath tumors or soft-tissue sarcoma [11]. Furthermore, vascular disease appears to contribute to the excess mortality of young patients [12].

In addition, about the half of the patients also have vascular lesions, however the pathogenesis of these lesions are not well defined. The vascular lesions have been described in the entire arterial tree, but involvement of the renal arteries is most common. NF1 vasculopathy of the cerebrum, endocrine system, gastrointestinal tract, and heart have also been reported. Frequently multiple vessels are involved [13]. In 1944 Reubi [14] classified the vascular histology into intimal, aneurismal and fusocellular forms. A common finding between the types is spindle cell proliferation. Other theories support that the vascular lesions are due to nerve proliferation within the vessel wall or from compression or invasion by neural tumors. More often, the histologic feature is fibromuscular dysplasia with a predominance of intimal thickening.

Salyer and Salyer [15] suggested that intimal thickening in NF1 vasculopathy is the result of proliferation of Schwann cells within the arteries. This implies a pathogenic relationship between these lesions and the neurofibromas that characterize this disease. Riccardi has suggested that NF1 vasculopathy results from a dysplastic process, in which abnormal function of neurofibromin alters vascular histogenesis.

Macroscopically, these lesions can take a variety of forms including vascular stenosis, aneurysms, and arteriovenous fistulae. In histological examination the small and medium sized vessels are presented with thickening of the intima and a thin but fibrotic media. The vascular structure in neurofibromatous tissue also has histological alterations with thin walled ecstatic blood vessels lying in a loose neural stroma, which replace the normal adipose tissue [2].

Coexisting coagulopathies may increase the complication rates. These may be inherited or secondary to vascular anomalies causing platelet trapping and consumption of clotting factors. Hemostasis can be difficult to obtain, following injury to these lesions. Diathermy is of limited use as the tissue is very friable [16-18].

Figure 12. The schematic view of a continuous loop-shaped suture ligation, from ref. [5].

Figure 13. Postoperative view 2 days after surgery, from ref. [5].

Figure 14. Postoperative result 12 months after surgery, from ref. [5].

Preoperative angiography and superselective embolization have been used in elective excision of vascular neurofibromas. The results of such treatment without associated surgery have been disappointing, because the tumors tend to revascularize quickly. It has been suggested that embolization therapy by a skilled interventional radiologist should be considered prior to elective excision of neurofibromas to reduce intraoperative blood loss. The most effective way to control the bleeding seems to be the ligation of the neurofibromata's vascular pedicle under direct vision of the feeding vessels and the external compression [3].

CONCLUSION

This chapter presents the experiences of the authors in 16 cases of giant neurofibroma, as well as a literature review of the surgical methods that have been used in giant neurofibroma surgery. The preservation of significant structures such as the facial nerve and the control of the intraoperative bleeding in the cases that, associated with vascular malformations, are important steps when excision of these tumors is decided. In our cases, two patients with neurofibroma of the upper limb required further reconstruction after the tumor excision; one of them required nerve graft to bridge the nerve defect, and a second patient required tendon transfer in order for the normal function of the hand to be restored. In one case of giant neurofibroma of the buttock, a novel method was performed to obtain a bloodless field using a continuous loop-shaped suture in order to ligate the base of the tumor. In addition, we presented several other approaches, methods and tools facilitating successful tumor surgery.

ABSTRACT

Patients with Neurofibromatosis 1 (NF 1) suffer from a myriad of medical problems including benign as well as malignant tumors. Malignancy is the most common cause of death in affected individuals, and reduces life expectancy by 10-15 years. Amongst other tumors, patients with NF1 carry an elevated risk of specific central nervous system (CNS) tumors. The most common NF1-associated CNS tumors are low-grade gliomas (LGG) such as optic pathway gliomas, hypothalamic gliomas, and other parenchymal gliomas located in the brainstem, cerebellar peduncles, globus pallidus, and midbrain. In addition to CNS tumors, patients with NF1 also develop peripheral nervous system (PNS) tumors such as neurofibromas and schwannomas. These tumors arise most commonly from major peripheral nerves such as the radial and ulnar nerve. These are benign tumors however can cause significant disfigurement, pain and depending on the location specific neurological complications. Malignant transformation of these tumors leads to malignant peripheral nerve sheath tumors (MPNST). These tumors occur in less than 5% of children with NF1, but are the leading cause of mortality in adult patients with NF1.

Significant advances in our understanding of LGG have been achieved over the last several years. Several genetic aberrations, which activate the MAPK pathway have been identified in the majority of LGGs, most notably the BRAF-KIA1549 fusion protein and the activating BRAFV600E mutation. Specific inhibitors of MEK1/2, the immediate downstream target of BRAF, are currently being tested in the clinic for children with LGGs. Treatment for symptomatic plexiform neurofibromas remains a clinical challenge for most pediatric neuro-oncologists. Recent studies have shown promise to use pegylated (PEG)-interferon-alpha-2b. Other treatment strategies also target the MAPK pathway for

these tumors. Treatment of MPNST remains under investigation and outcome remains poor. Most patients are currently treated with a combination of surgery, radiation and chemotherapy.

In this chapter, we will outline NF1 associated CNS and PNS tumors and discuss current treatment approaches.

INTRODUCTION

Neurofibromatosis 1 (NF1) is a genetic syndrome due to loss-of-function of the NF1 gene that encodes neurofibromin [1]. NF1 is a tumor suppressor gene that is a negative regulator of the RAS signaling cascade [2]. Loss of neurofibromin results in increased activity of ras, which leads to tumorigenesis [3]. The incidence of NF1 is estimated to be about 1 in 3000 [4]. Patients with NF1 suffer from a myriad of medical problems, including benign as well as malignant tumors [5].

Malignancy is the most common cause of death in affected individuals and reduces life expectancy by 10-15 years [6]. Amongst other tumors, patients with NF1 carry an elevated risk of specific central nervous system (CNS) tumors. The most common NF1-associated CNS tumors are low-grade gliomas (LGG), such as optic pathway gliomas, hypothalamic gliomas, and other parenchymal gliomas located in the brainstem, cerebellar peduncles, globus pallidus, and midbrain [7, 8, 9]. In addition to CNS tumors, patients with NF1 also develop peripheral nervous system (PNS) tumors, such as neurofibromas and schwannomas [6]. These tumors arise most commonly from major peripheral nerves such as the radial and ulnar nerve. While these tumors are typically low-grade, they can cause significant disfigurement, pain and other neurological complications. Further, malignant transformation of these tumors leads to malignant peripheral nerve sheath tumors (MPNST). MPNSTs occur in less than 5% of children with NF1, but are the leading cause of mortality in adult patients with NF1 [6].

Significant advances in our understanding of these tumors have been achieved in recent years. Several genetic aberrations, which upregulate the RAS pathway and activate VEGF, play a role in the tumorigenesis of these tumors. In addition, mutations that activate the MAPK pathway have been identified in pediatric LGGs, most notably the BRAF-KIAA1549 fusion protein and the activating BRAF^{V600E} mutation [10, 11, 12, 13, 14], however these might be less common in patients with NF1 [12, 15, 16, 17]. These identified mutations might play a role as biomarkers, and identification of these pathways has led to new therapeutic developments that are currently being tested in clinical trials. For instance, specific inhibitors of MEK1/2, the immediate downstream target of BRAF, are currently being tested in the clinic for children with LGGs via the Pediatric Brain Tumor Consortium (PBTC). Treatment for symptomatic plexiform neurofibromas remains a clinical challenge for pediatric neuro-oncologists [18], but recent studies have shown promise in the use of PEG-interferon-alpha-2b [19, 20]. To date we have not yet identified an effective treatment strategy for patients with MPNST, and patients are often treated on clinical trials with a combination of surgery, radiation and chemotherapy.

In this chapter, we outline NF1 associated CNS and PNS tumors, and discuss current treatment approaches.

CENTRAL NERVOUS SYSTEM TUMORS IN CHILDREN WITH NF1

The most common NF1-associated CNS tumors are optic pathway gliomas (OPG) and hypothalamic gliomas, as well as other parenchymal gliomas located in the brainstem, cerebellar peduncles, globus pallidus, and midbrain [7, 8, 9]. OPGs are the most common CNS tumors in patients with NF1, occurring in up to 15% of children with NF1 [21, 22, 23]. In patients with symptomatic OPGs, the risk of developing other glial tumors in the CNS is nine times more frequent than in patients without symptomatic OPGs [24].

Figure 1. Optic Glioma. Coronal T2-weighted magnetic resonance imaging (MRI) scan demonstrating right optic glioma. Note enlargement of the optic nerve.

Low Grade Glioma: Clinical Presentation

OPGs can occur anywhere along the optic tract. In most patients, these tumors are asymptomatic, but about one third of patients will develop symptoms, including vision loss or proptosis. Other clinical findings include abnormal color vision, optic atrophy and afferent pupillary defect. In addition, precocious puberty can be seen in OPGs involving the optic

chiasm and the hypothalamus [25, 26]. In general, children become symptomatic of these tumors within the first decade of life [27]. About 50% of children with NF1 and OPG will develop vision loss. Consequently, close clinical observation is typically done for initial management [23]. A recent retrospective, multi-center study evaluated visual outcomes in patients following chemotherapy for NF1-associated OPG. Mean age of diagnosis of OPG was 2.66 years, age of first chemotherapy dose median was 4.04 years with a median range of diagnosis to treatment being 133 days. Outcomes were assessed at the completion of therapy: about one third of patients had improved visual acuity and 40% had stable visual acuity. While most subjects experienced stabilization or improvement in vision after therapy, visual acuity worsened in 28% of subjects after treatment. The most consistent prognostic factor for poor visual outcome was tumor involvement of the optic tracts or radiations ($P = .02$ per subject) and optic pallor at the start of treatment ($P = .005$ per eye). Age was another prognostic factor for poor visual outcome, with subjects younger than 2 years or older than 5 years more likely to have a decline in visual acuity. Further, none of the children younger than 2 years of age demonstrated any improvement in visual acuity with treatment. Of note, there was a poor correlation between radiographic outcome and visual acuity outcome; as many as 25% of patients with complete response or partial response by MRI had worsening of visual acuity, and 29% with stable disease or minor response showed worsening of visual acuity, thus calling into question the utility of MRI as adequate measure of visual outcome [23].

Other LGGs that occur in patients with NF1, though less commonly than OPGs, include astrocytomas and ependymomas, and are located within the cerebellum, brainstem, deep grey nuclei, and spinal cord [28]. Like OPGs, these low-grade gliomas tend to have a better prognosis in NF-1 patients as compared to non-NF1 patients [29]. This is true regardless of location including brainstem tumors [30, 31]. NF1 patients with brainstem gliomas tend to have more indolent courses. A study of 17 patients with NF1 and brainstem tumors indicated that the medulla was most commonly involved structure, in 82% of these patients, in contrast to the pontine location as more commonly occurs in non-NF1 patients [30]. Median follow-up was 52 months; 15 of 17 patients remained alive, and 14 of those did not require adjuvant chemotherapy [30]. Another study described 23 NF1 patients with brainstem tumors with a median follow-up period of 67 months for 17 of 23 patients who were untreated and 102 months for the six of 23 patients who received therapy; only one previously untreated patient experienced radiographic and clinical progression, and all but one remain alive [32].

Low Grade Glioma: Imaging Characteristics

The characteristics of optic pathway glioma are often apparent on head CT scans, however; MRI is the preferred method and current clinical standard for diagnosis and follow up imaging. CT characteristics include enlargement of the optic nerve(s), chiasm or tract. Further, there can be changes to the bony structures of the optic canal and sphenoid wing [33, 34]. MRI T2-weighted imaging more clearly delineates anatomic changes including enlargement of the optic nerve(s) (Figure 1), chiasm (Figure 2) or tract. In addition, both homogenous and heterogenous contrast enhancement can be seen [33, 35, 36]. Other characteristics include a cystic component to the tumor, as well as mass effect on adjacent structures [37]. Other parenchymal lesions, such as gliomas involving the thalami and basal ganglia, appear as hyperintense T2 lesions that may or may not be enhancing [35, 36].

Figure 2. Low-grade Glioma. Coronal T2-weighted MRI (left) and T1-weighted MRI (right) demonstrating low-grade glioma of optic chiasm. Note enlargement of the optic chiasm.

Low Grade Glioma: Prognosis

OPG tumors are common and the natural history demonstrates often follows a benign course and some tumors may even regress after initial diagnosis [38]. The overall 5-year survival rate is 90% at 5 years [37]. However, these tumors may lead to symptoms, typically visual loss and hypothalamic dysfunction such as precocious puberty. The highest-risk period for the development of symptomatic OPGs in NF1 patients is during the first 6 years of life [39], and further, ages <2 years or >5 years are poor prognostic factors [23]. Screening MRIs of asymptomatic children remains controversial since it has not been proven effective in reducing complications related to OPGs [39]. Further, a recent study demonstrated a poor correlation between radiographic outcome and visual acuity outcome [23]. Thus, functional outcomes are of highest importance, and yearly ophthalmological evaluation is indicated in younger children, and older children should undergo sporadic ophthalmological evaluations [39]. OPGs that present in older patients are more likely to progress compared to younger patients under age 10 years [39]. Other features associated with shorter survival aside from diagnosis in adulthood include extra-optic location and symptomatic tumors [37]. Of note, symptomatic and/or progressive tumors are often found to be of more aggressive histologic subtype [37]. Brainstem glioma and optic pathway glioma tend to be less aggressive in NF1 patients than in non-NF1 patients [30, 40]; in a study of 23 patients with OPG, only 1 patient with NF1 and OPG died due to disease progression, whereas 7 of 39 non-NF1 patients died ($p=.045$) [40].

Low Grade Glioma: Treatment Modalities

1. Role of Surgery

For lesions that are easily resectable, such as LGGs located within the posterior fossa, surgery is standard of care and often curative. Conservative treatment such as serial

neuroimaging and serial ophthalmological evaluations, however, is often preferred for most asymptomatic LGGs for which complete surgical resection cannot be achieved without significant morbidity such as OPG or midline LGG. In these cases, surgery is reserved for those with radiographic progression or associated severe symptoms [7], e.g., significant or complete visual loss, severe proptosis or strabismus, or associated hydrocephalus [7]. Cerebrospinal fluid shunts are used when patients are symptomatic from hydrocephalus [37].

2. Radiation Therapy

Most centers avoid radiation therapy as a first-line treatment in young children with NF1, and only patients who have failed initial chemotherapy options are considered for radiation therapy. Various doses of radiation therapy have been used in the treatment of OPGs, and while tumor control is attained in up to 80-90% of patients with NF1 [41, 42], this type of treatment is associated with significant delayed morbidity, including neuro-cognitive decline, radiation-induced vasculopathies and endocrinopathies, such as deficiency in growth hormone [43]. Currently the rate of malignant transformation in pediatric LGG is not well characterized since biopsies at recurrence are rarely performed for these patients. While the risk of spontaneous transformation of LGG might be rare in pediatric patients [44], it has been noted in patients treated with radiation therapy [41, 45]. A study examining 82 tumors in 18 NF1 patients at a median age of 25 years (range, 4.3-64 years) showed that the most common reason to initiate radiation therapy was radiographic evidence of growth. 67% of patients received radiation therapy. Of all NF1 patients, the overall survival at 5 years was 94%. Five patients with NF1 were treated for LGG, which accounted for 11% of the tumors. Two of these patients developed malignant transformation of tumors, and both of these patients subsequently died [41]. Given these significant morbidities, radiation therapy is often avoided in children with NF1, unless they fail other treatment modalities.

3. Chemotherapy

Conventional chemotherapy is used effectively, particularly in young patients under age 5 years old in whom radiation therapy poses significant morbidity [27, 46]. Carboplatin and vincristine are the two agents most commonly used together, resulting in stabilization or reduction of tumor, with a beneficial 3-year progression-free survival (PFS) [19]. A recent study involving children with progressive or residual LGGs were randomly assigned to receive either a combination of carboplatin and vincristine, or a combination of thioguanine, procarbazine, lomustine, and vincristine (TPCV). Among all children, the 5-year event-free survival and overall survival were both higher for those receiving TPCV. This study also included a nonrandomized arm for patients with NF1, the results of which are to be reported separately [47]. Given the loss of a known tumor suppressor gene as occurs in NF1, there is concern that NF1 patients are at higher risk for transformation of residual or progressive tumor to a more aggressive phenotype after alkylating chemotherapy, as this has been reported in two patients occurring in the absence of radiation therapy and within 4 months of receiving chemotherapy [48]. Other agents that are currently being used for patients with LGG include vinblastine, the combination of bevacizumab and irinotecan, as well as temozolomide [49, 50, 51]. Weekly treatment with vinblastine for one year resulted in a 5-year PFS in a phase II trial of $42.3\% \pm 7.2\%$ and was in general well-tolerated, thus seems to be a good alternative to radiation therapy in pediatric patients with LGG who have failed other chemotherapy [50]. In children with multiple recurrent LGG treated with the combination of bevacizumab and

irinotecan every 2 weeks, 7 of 10 had an objective neuroradio-graphic response after two cycles of treatment, and 7 of 10 demonstrated clinical improvements, the majority with a lasting response, and this combination is reasonably well-tolerated. Of these patients, 6 of 10 remained on treatment for up to 22 months after treatment initiation [51].

4. Targeted Therapy

PI3K/mTOR Pathway: TOR is an evolutionarily conserved serine/threonine protein kinase; it plays an important role in cell growth and proliferation across species [52]. Mammalian TOR (mTOR) controls a variety of cellular processes involving regulation of growth factors and energy [52]. mTOR signals downstream targets within the PI3K/AKT pathway. This pathway is known to be dysregulated in a wide spectrum of human cancers through loss/mutation of PTEN as a negative regulator, PI3K mutation/amplification, AKT/PKB overexpression, and modulation of TSC1/TSC2 tumor suppressors. In addition, activation of the PI3K/AKT/mTOR pathway is frequently a characteristic of worsening prognosis through increased aggressiveness, resistance to treatment and progression. As such, mTOR inhibition might be an effective treatment strategy for LGG [53]. NF1-related low-grade astrocytomas exhibit increased levels of mTOR pathway activation, demonstrated by western blot analysis assessing phospho-S6, a marker reflecting mTOR activation [54]. A current trial is investigating the potential benefit of mTOR inhibitor everolimus in children with chemotherapy-refractory progressive or recurrent LGGs, including children with NF1. Results of this trial are pending. (www.poeticphase1.org).

RAS-MAPK Pathway

Neurofibromin, encoded by the NF1 gene, is a GTPase-activating protein (GAP). It acts as a tumor suppressor by negatively regulating RAS pathway output by the conversion of active RAS-GTP to inactive RAS-GPD [55]. Thus lack of NF1 results in increased RAS activity leading to dysregulated cell growth. There are three important isoforms of RAS: K-RAS, N-RAS, and H-RAS. It has been demonstrated that activation of the K-RAS isoform leads to a proliferative advantage seen in astrocytes [56]. Further, K-RAS has been shown to modulate the RAF/mitogen-activated protein kinase (MAPK)/extracellular signal-regulated kinase (ERK) pathway; typically, increased RAS activity results in increased signal transduction via this pathway. One avenue for possible therapeutics for LGGs involves targeting the MAPK pathway. Antibodies that block the MAPK-ERK pathway in the Nf1:p53 mouse tumor model cell lines *in vivo* have been demonstrated to block EGFR-stimulated tumor cell line growth [57]. Recent advances investigating the underlying oncogenic events in pediatric LGG have led to the discovery of activating mutations in BRAF, a member of the RAF family of serine/threonine protein kinases. The RAS-MAPK signaling pathway utilizes a series of kinases to relay signals from the cell membrane to the nucleus, playing important roles in cell proliferation, differentiation, cell-cycle arrest, and apoptosis [58]. In pediatric LGG, particularly in pilocytic astrocytomas, a copy number gain of 2 Mb at the chromosomal region 7q34 has been identified. This copy number results in a fusion of the genes KIAA1549 and BRAF, and leads to constitutive activation of BRAF due to loss of the Ras-binding domain of BRAF [13, 16, 59]. BRAF activation leads to phosphorylation of MEK1/2, which in turn phosphorylates ERK. The various KIAA1549-BRAF fusion genes are thought to be functionally similar, all possessing the BRAF kinase domain, while the NH2 terminus is

replaced by KIAA1549, implying that the fusion protein is constitutively activated, leading to high levels of phosphorylated MEK and ERK [60].

In a study of 106 LGG (grade I-II) from primarily pediatric patients, including pilocytic astrocytomas, low-grade glioneuronal/neuroepithelial tumors, pleomorphic xanthoastrocytomas, diffuse astrocytomas, pilomyxoid astrocytoma, and unclassifiable low-grade gliomas, KIAA1549-BRAF fusions were identified by sequencing in nearly 50% of tumors overall and were found in the majority of pilocytic astrocytomas [61]. Importantly, no KIAA1549: BRAF fusions were seen as higher-grade tumors (five high-grade astrocytomas, four medulloblastomas, two ependymomas, and one dysembryoplastic neuroectodermal tumor were tested) [61]. Of note, in this cohort of patients, 5% had a clinical diagnosis of neurofibromatosis, and all of these lacked BRAF alterations [61]. Identification of KIAA1549 - BRAF fusion may be an important molecular marker to help in distinguishing pilocytic astrocytomas and other tumors such as low-grade diffuse astrocytomas and mixed oligoastrocytomas grade II, as these fusion products are detected in 80% of pilocytic astrocytomas but only infrequently in these other tumors [60]. However, classifying pediatric LGG based on specific molecular aberrations is still subject of debate and additional research is required.

BRAF rearrangements have been shown to be an independent favorable prognostic factor in pediatric LGG [62]. In a study of 70 pediatric low-grade astrocytomas compared with 76 control tumors, five-year PFS was 61% for BRAF-KIAA1549 fusion-positive compared with 18% for fusion-negative patients ($P=0.0004$) [62]. Further, it has been demonstrated that pediatric gliomas demonstrate activating point mutations of BRAF, the BRAF^{V600E} mutation [12]. The BRAF^{V600E} mutation is found in approximately 60% of pleomorphic xanthoastrocytomas and 10–15% of pediatric astrocytomas, but are also seen in pediatric gangliogliomas [12, 15, 16, 17]. In addition to BRAF mutations, other targets along the MAPK signaling pathway include K-RAS, PTPN11, MEK1/2, and H-RAS. In some pilocytic astrocytomas, the SRGAP3-RAF1 gene fusion, as well as activating mutations in KRAS, have been identified [13, 59]. Additional studies are needed to inquire how common these mutations are in NF1-associated tumors.

MEK inhibitors are currently introduced in clinical trials for other types of tumors, such as melanoma and lung cancer. Given the upregulation of the MAPK pathway in pediatric LGG, an ongoing study from the Pediatric Brain Tumor consortium is currently testing a MEK inhibitor for the treatment of pediatric progressive LGG including children with NF1 (www.pbtc.org).

PERIPHERAL NERVOUS SYSTEM TUMORS IN CHILDREN WITH NF1

In addition to CNS tumors, patients with NF1 also develop peripheral nervous system (PNS) tumors such as neurofibromas and schwannomas [6]. These tumors arise most commonly from major peripheral nerves such as the radial and ulnar nerve. While benign, these tumors can cause significant disfiguration, pain and other neurological complications. Malignant transformation to malignant peripheral nerve sheath tumors (MPNST) can occur. These occur in less than 5% of children with NF1, but are the leading cause of mortality in adult patients with NF1 [6].

Figure 3. Plexiform Neurofibroma. Axial T2-weighted MRI (top) and T1-weighted post-contrast MRI (bottom) demonstrating large, diffuse, infiltrating plexiform neurofibroma involving the left sacral plexus extending into the left sacral neural foramina.

Plexiform Neurofibromas: Clinical Presentation

Neurofibromas are comprised of a mixture of fibroblasts, pericytes and proliferated Schwann cells [63]. Schwann cells are thought to be the primary pathogenic cell in neurofibromas [64]. These tumors originate from within the nerve, expanding that portion of nerve, and are well-circumscribed. Neurofibromas in NF1 patients can be classified as cutaneous neurofibromas, subcutaneous neurofibromas and plexiform neurofibromas (PNs).

Cutaneous and subcutaneous neurofibromas arise at the nerve terminus or just beneath the skin. The size ranges from only millimeters to large enough to be disfiguring. Localized cutaneous neurofibromas are the most common clinicopathologic subtype. These can be colored and are typically soft. The subcutaneous neurofibromas are sometimes firm, tender, palpable nodules under the skin. Both can vary in number from just a few to innumerable in any given patient and typically appear in late childhood or early adolescence [65]. PNs occur in over 50% of people with NF1 [66]. These can be nodular or diffuse. Nodular PNs arise from nerves or organs beneath the skin, commonly clustering around proximal nerve roots with the potential to extend through the neural foramina and compress the spinal cord. Diffuse PNs involve multiple nerves, often expanding into surrounding tissues and organs. The overlying

skin is often thickened and hyperpigmented. Diffuse PNs tend to enlarge with age and can become disfiguring. As such, they may limit range of motion or function of involved limbs or organs [27].

Plexiform Neurofibromas: Imaging Characteristics

Neuroimaging can determine the precise nerves involved or the extent of involvement of peripheral nerve sheath tumors (Figure 3). Certain subsets of these tumors have a typical appearance on imaging. For instance, nodular PN take on a classic “dumbbell” appearance on neuroimaging [27]. Imaging can sometimes be helpful for determining the transformation from benign to malignant peripheral nerve sheath tumors, as characteristics such as rapid growth compared to prior radiographic appearance, avid enhancement and invasion of surrounding structures correlate with malignancy. However, these qualitative measures may be difficult to assess at times, thus necessitating biopsy [7, 67].

Plexiform Neurofibromas: Prognosis

Treatment of plexiform neurofibromas remains challenging. The natural history of these tumors is not well understood. One study showed that PN can remain stable in older individuals, but have a higher tendency for growth in children < 21 years of age. These tumors tend to grow and enlarge over time, with no proven medical therapies to reduce or prevent their growth [27]. A recent study followed 34 NF1 patients with a total of 44 tumors with longitudinal MRI scans over 16 years. Most of the PN in this study were small (<10 cm²), but notably the largest tumors occurred in children younger than 13 years of age. Further, neurofibromas in younger patients grew faster than neurofibromas from older patients; in children younger than 13 years of age, growth of 2 cm²/ year or more in 30% of tumors was observed. This study followed 18 patients with NF1 younger than 10 years of age; only 33% of the 23 tumors were symptomatic. These findings may suggest that MRI screening for PN in younger NF1 patients may be valuable. Also in this study, superficial plexiform neurofibromas were observed to grow more rapidly than deep PNs ($p=.034$), implying that tumor location may affect growth. In patients with multiple PNs, the growth of each tumor often differed; this underscores the importance of following each tumor within an individual separately, as rate of growth of one tumor cannot be used to represent the rate of growth of all tumors within any given patient [66]. Of all of the patients followed, one adult man with a superficial and invasive PN developed pain and was found to have substantial tumor growth; this tumor was biopsied and found to be an MPNST [66].

Plexiform Neurofibromas: Treatment Modalities

1. Role of Surgery

Surgical excision has been the mainstay of treatment of PNS tumors such as neurofibromas, particularly for those tumors causing severe pain or weakness, thus indicating compression of

nerves or the spinal cord itself, or involvement of surrounding tissues. However, the associated morbidities of nerve injury, hemorrhage and tumor recurrence are significant, and thereby limit surgical management only to those patients with intolerable symptoms [27]. As they infiltrate surrounding tissues, complete surgical resection is often not possible [27] and tumor regrowth is common. In a retrospective review of 121 NF1 patients with 168 tumors over 20 years at a pediatric referral center who underwent a total of 302 surgical procedures, 74 of the 168 tumors (44%) all progressed after the first procedure [68]. A subgroup analysis revealed that 60.2% of children age 10 years or less had tumor progression after the first procedure, compared with 31.2% of children older than 10 years of age ($p=.0004$). Of the 25 cases of complete tumor resection, only 5 (20%) progressed, compared with 39.5% progression among those tumors with a near-total resection. By contrast, 74 tumors had a subtotal resection, defined as 50-90% resection, with 33 (44.6%) of these tumors progressing; 21 of 31 (67.7%) tumors with a <50% resection progressed after the first procedure ($p<.0001$ log rank). Of note, for those tumors that did progress, the median time to progression was increased the more extensive the resection (<2 years time to progression for those with <50% resection compared with >10 year time to progression for those tumors with near-total resection) [68].

2. Radiation Therapy

Certain patients are not ideal candidates for surgery, particularly those with advanced age, tumor location precluding surgical resection or other comorbidities. Stereotactic radiosurgery is a potential treatment option for benign lesions, though less data exist in support of this as compared with radiotherapy for malignant tumors. Further, secondary neoplasia and radiation-induced changes, such as myelopathy, remain a concern [69]. Despite these potential morbidities, image-guided radiosurgery is being used to treat benign tumors, including neurofibromas, particularly in those patients for whom surgery is not an option. A study reported greater than 95% long-term control as long as 48 months, as demonstrated by imaging, of 46 benign spinal cord tumors including neurofibromas, schwannomas and meningiomas treated with radiosurgery [69]. In this study, nearly 90% of the neurofibromas occurred in confirmed NF1 patients. Of all of the tumors in this study, the neurofibromas showed the poorest clinical response, with only 18% showing reduction in tumor volume [69]. This may indicate that neurofibromas respond more poorly to radiation therapy than do other tumor histologies.

3. Chemotherapy

Chemotherapy is generally not effective, and various clinical trials have not led to a standard medical treatment [18]. Early studies were performed using the antihistamine agent ketotifen fumarate, but variability in entry criteria as well as subjective endpoints make interpretation of efficacy of this medication not possible [18]. A prospective trial for treatment was a randomized phase II trial for PN, which examined cis-retinoic acid or interferon. This trial enrolled both children and adults, though the mean age of participants was 11 years. Participants were enrolled if they had progressive PN at time of entry, and tumors were monitored with serial imaging. While 96% of patients treated with interferon were stable at 18 months, no patient had a significant radiographic response; 14% of patients described symptomatic improvement, and 8% demonstrated minor tumor shrinkage on imaging [18]. A phase I trial using thalidomide, an anti-angiogenic agent, in patients with PN was recently completed [18, 70].

4. Targeted Therapy

a) mTOR Pathway

Blocking mTOR may slow or stop tumor growth in patients with NF1. An ongoing trial is examining the role of sirolimus, an mTOR inhibitor, to treat PN in patients with NF1 (study number NCT00652990).

Interferon Treatment

Interferons have been shown to have antitumor effects *in vitro* by both antiproliferative and antiangiogenic properties. These cytokines are secreted proteins that defend the host against infectious agents, such as viruses and parasites, but also affect immune functioning, cell proliferation, and cell differentiation. Treatment with interferons have been proven effective *in vivo* in a variety of human diseases, including hairy cell leukemia, Kaposi's sarcoma, non-Hodgkin's lymphoma, and chronic myelogenous leukemia [19]. A recent study looked at the role of interferons in neurofibromas. Thirty patients were enrolled, with a median age of 9.3 years, with progressive, symptomatic, unresectable, or life-threatening PN. Twelve of these patients received their recommended phase II dose of pegylated interferon- α -2b (PI) of 1 μ g/kg/wk. The PI was administered weekly and continued for up to 2 years. This study demonstrated that children with PN showed disease stabilization; further, 29% of patients who underwent volumetric analysis had a 15-22% decrease in volume with interferon [20].

b) Anti-angiogenic Treatment

Angiogenesis plays a role in tumor formation in NF1. RAS mutations upregulate vascular endothelial growth factor (VEGF) expression [71]. In addition, fibroblast growth factor (FGF) is highly expressed in neurofibromas [72]. Thus, anti-angiogenic treatment is another potential treatment intervention. A current clinical trial is examining local injection of ranibizumab, a VEGF inhibitor, into neurofibromas compared with control (saline) on tumor volume (study number NCT00657202). Inhibition of survival pathways, such as blocking the epidermal growth factor receptor (EGFR) signaling cascade, has been shown to be effective in *in vitro* models of neurofibromas. Growth of neurofibroma cells *in vitro* in the Nf1:p53 mouse tumor model could be blocked by an EGFR antagonist AG1478, which is a cell-permeable member of the tyrphostin family that binds tightly to the catalytic domain of the EGFR, inhibiting its tyrosine-specific protein kinase activity [56]. Further, NF1+/- p53 +/- mice that develop sarcomas have shown improved survival when EGFR expression was reduced genetically [73].

c) Tyrosine Kinase Inhibitor Treatment

Imatinib mesylate is a receptor tyrosine kinase inhibitor that targets platelet-derived growth factor receptor (PDGFR) expressed on Schwann cells and blood vessels. Imatinib significantly reduced Schwann cell viability in those cells derived from human PN *in vitro* after treatment for 28 days [74]. A pilot study is currently ongoing to examine the efficacy of imatinib mesylate in NF1 patients with plexiform neurofibromas (study number NCT01140360). A phase I trial of the raf kinase and receptor tyrosine kinase inhibitor sorafenib in children and young adults with NF1 and inoperable neurofibroma is completed with results pending (study number NCT00727233). Further, a phase II trial of pirfenidone, an anti-inflammatory and anti-fibrotic agent, in children is completed with results pending (study number NCT00076102).

Figure 4. Malignant Peripheral Nerve Sheath Tumor. Coronal T2-weighted MRI (left) and T1-weighted post-contrast MRI (right) demonstrating large, extensive, multilobar conglomerate mass of the left neck involving the left retropharyngeal, carotid, and suboccipital spaces. Note the heterogeneous enhancement of the mass seen on the T1-weighted post-contrast scan.

Malignant Peripheral Nerve Sheath Tumor (MPNST): Clinical Presentation

PN can undergo malignant transformation to MPSNTs. These are aggressive tumors that are often fatal despite intensive therapy. These occur in less than 5% of patients with NF1 [6, 67] at a mean age of 28.7 years [75]. Rapid or asymmetric growth, often accompanied by pain, can be signs of malignant transformation. Despite imaging or tissue sampling, diagnosis can be difficult, as biopsy may miss a malignant component of a large tumor [7]. Further, the ability to diagnose MPNST has suffered from lack of specific morphological, immunohistochemical and molecular criteria and tests [76]. Neurofibromas can occur anywhere in the body in patients with NF1, and at least 40% of affected adults have internal neurofibromas, which may not be apparent on physical examination, thus the use of whole-body MRI to characterize tumor burden may be helpful. In a study of NF1 patients with MPNSTs and age- and sex-matched NF1 patients without MPNSTs, internal neurofibromas were detected with whole-body MRI in 100% of the NF1 patients with MPNST under the age of 30, thus advocating the use of whole-body MRI in young patients with NF1 to detect internal tumors which have malignant potential. In addition, there is an association between the median number of subcutaneous neurofibromas in NF1 patients and the occurrence of MPNSTs overall [77].

A grading system separates low-grade from high-grade MPNST. Roughly 85% of these tumors fall into the high-grade category, characterized by cytologic atypia, high numbers of mitoses, and hypercellularity with or without necrosis [76].

MPNST: Imaging Characteristics

Malignant transformation of PNs to MPNSTs remains a challenging problem to diagnose and manage. PNs are carefully followed by MRI or CT, and patients are monitored for features of malignancy including unremitting pain or a rapid increase in tumor size [78]. MRI is used for tumor surveillance but often does not reliably differentiate malignant from non-malignant tissue [7]. Imaging characteristics of malignant transformation include rapid growth of tumors and ill-defined margins, as well as invasion into surrounding structures (Figure 4) [7, 79].

A recent study examined the predictive value of [18 F]-fluorodeoxyglucose (FDG) positron emission tomography (PET) to identify malignant transformation of PN in children with NF1 and found that with a pre-defined standard uptake value, sensitivity and specificity for determining benign from malignant tumors were 1.0 and 0.94, respectively [80]. This indicates that FDG-PET may be a useful imaging modality to follow PNs at risk for malignant transformation.

MPNST: Prognosis

These tumors are the leading cause of mortality in adult patients with NF1, as the lifetime risk increases to up to 13% [6, 67]. Median survival is about 30 months among children 1-17 years of age with MPNST [81], and five-year survival is only 16% [75]. Of note, NF1 patients tend to have a worse outcome with statistically significant lower disease-free survival than non-NF1 patients, with more recurrences and ultimately deaths [82]. Numerous studies cite disease-specific survival for NF1 patients with MPNST 16-38%, compared with 42-57% in non-NF1 patients [83].

MPNST: Treatment Modalities

1. Role of Surgery

Complete surgical resection of MPNST is the mainstay of treatment and is a strong predictor of long-term survival. Achieving tumor-free histological margins is the goal in every NF1 patient. However, MPNSTs are very aggressive tumors with common local recurrences even in spite of tumor-free margins. In addition, the location of these tumors sometimes can preclude complete resection; MPNSTs affecting the head and neck are rarely amenable to gross total resection without resulting in significant associated disfigurement and deformation of surrounding structures [84].

2. Radiation Therapy

Radiotherapy is generally recommended for all MPNST [82]. This may be an important adjunct to surgical therapy to prevent local recurrence. A recent study examining 175 patients with MPNST over 25 years revealed higher disease-specific survival (DSS) of 60% at 5 years and 45% 10 years, compared with DSS reported in the literature of 34-52% and 22-34% respectively, likely related to better local control attributable to aggressive surgical resection followed by radiation therapy [83].

3. Chemotherapy

The role of chemotherapy in treatment of MPNST remains controversial, given the lack of sufficient data. There have been no controlled studies evaluating the role of chemotherapy alone in patients with MPNST [82]. Despite this, chemotherapy is generally used in combination with surgery and radiation to treat MPNST. Several agents have been reported including gemcitabine, docetaxel, caboplatin, etoposide, dactinomycin, cisplatin, vincristine, cyclophosphamide, imidazole carboxamide, doxorubicin, and ifosfamide, but overall, the clinical benefits of each agent have been variable and thus inconclusive [82]. As these tumors have such a poor prognosis, most centers recommend early, aggressive, multi-modal therapy, including chemotherapy. A study evaluating the roles of the chemotherapeutic agents doxorubicin and ifosfamide, along with surgery and radiation therapy, demonstrated a two-year survival of 80% in patients with MPNST, which is higher than the reported rates of 54-73% from other studies of non-chemotherapeutic treatments [82].

4. Targeted Therapy

a) Tyrosine Kinase Inhibitor Treatment

A recent trial using imatinib mesylate to treat patients with MPNST was terminated early due to slow recruitment and lack of response (study number NCT00427583).

b) Angiogenic Pathways

VEGF expression is also increased in MPNSTs [85]. It was shown *in vitro* that tumor angiogenesis is related to the malignant potential of MPNSTs, which correlates to increased VEGF expression [85]. *In vivo* treatment of human NF-1 malignant neurogenic sarcoma xenografts with VEGF receptor inhibitor (SU5416) demonstrated reduced angiogenesis and reduced tumor volume, with reduction in tumor cell proliferation and increase in apoptosis [85].

c) Cytoskeletal Remodeling

A recent study examined single-nucleotide polymorphism (SNP) genotyping and copy number alteration (CNA), loss-of-heterozygosity (LOH), and copy number neutral-LOH (CNN-LOH) analyses of DNA from 15 MPNSTs, five PNs, and patient-matched lymphocyte DNA. MPNSTs, but not PNs, were found to have high-level CNN-LOH. The genes involved in the MPNST CNAs included the ITGB8, PDGFA, Ras-related C3 botulinum toxin substrate 1 (RAC1) (7p21-p22), PDGFRL (8p22-p21.3), and matrix metalloproteinase 12 (MMP12) (11q22.3) genes. The pathways involved in alteration of these genes included amplification of the Ras-homologous (Rho-) GTPase signaling pathway. Rho-GTPases are regulators of actin organization, cell motility, cell-cell adhesion, cell-extracellular matrix adhesion, cell cycle progression, and apoptosis, which are key processes involved in malignant transformation and metastasis. Thus, these copy number gains may play a role in malignant transformation of benign tumors such as PNs. Further, specific inhibitors of parts of the Rho-GTPase pathway may reduce the malignant potential of these cells [86]. These are potential new treatment strategies for treating MPNST.

CONCLUSION

In recent years, a number of novel molecular targets have been identified in tumors associated with NF1. Developing targeted therapies that exploit these biological vulnerabilities holds the promise of not only prolonging the life of patients affected with NF1, but also reducing the significant side effects associated with current therapies such as traditional chemotherapy and radiation therapy.

ABSTRACT

Optic pathway gliomas (OPG) occur in 15% of children with Neurofibromatosis type 1 (NF1) and will lead to visual deficits in up to half. Because this tumor rarely threatens life but often leads to uncorrectable and permanent vision loss, preserving vision is the primary objective in management of OPGs. However, measuring visual function with ophthalmology exams can be challenging in young children with NF1-associated OPG. Recently, a variety of surrogate outcome measures have been investigated to determine if reliable quantifiable markers of vision can be found.

In this chapter, we review the presentation and management of OPGs in children with NF1. We discuss endpoints commonly used in clinical trials, including assessments of visual function and radiologic progression. Finally, we investigate and compare recent putative surrogates of vision in OPG, and we discuss their utility in identifying and following vision loss in children with NF1.

Currently, visual acuity is the most reliable, comparable and quantifiable outcome measure available in the assessment of patients with OPG. However, novel physiologic and radiologic markers of vision loss may offer an important adjunct to the assessment of the child with NF1-associated OPG in the future.

INTRODUCTION

The most common brain tumor in children with Neurofibromatosis type 1 (NF1) is the optic pathway glioma (OPG), [1] a low-grade neoplasm that can involve any part of the precortical visual pathway, including the optic nerves, chiasm, tracts and radiations. This tumor accounts for 2 to 5% of all brain tumors in childhood, [2] but it affects as many as 15–20% of children with NF1. [3-5] OPGs can cause uncorrectable vision loss, proptosis, and hypothalamic dysfunction. Some degree of vision loss occurs in up to 50% of children with this tumor. [6, 7] Identifying individuals that require treatment, and in some patients measuring the extent of visual deficits, are challenges in NF1-associated OPGs.

The development of clinically useful endpoints for OPGs is hampered by a lack of consensus in the management of these tumors. In a survey of 10 leading NF1 centers, Fisher et al. [8] demonstrated the variability in treatment indications for OPG. Although most OPG patients were treated for some degree of vision loss, treatment was often initiated for a variety of other indications, including tumor characteristics (growth, size, location, or enhancement on MRI), optic disc changes (pallor or swelling) and unreliability of the visual exam. There also appeared to be a lack of consensus among institutions regarding the relative importance of these variables. Thus, it has been difficult to develop meaningful and uniform outcome measures to help guide treatment decisions. Many clinical trials use radiologic progression as their sole endpoint — a less clinically relevant endpoint than visual acuity loss or other neurologic or endocrine dysfunction. Currently, an international collaborative effort is underway to better define clinically relevant endpoints in OPG with an emphasis on visual acuity (Response Evaluation in Neurofibromatosis and Schwannomatosis, REiNS, <http://www.reinscollaboration.org>). In addition, Avery et al. have recently outlined appropriate visual acuity testing methods across the age spectrum to further the development of OPG research and therapies. [9]

Designing clinically relevant outcome markers for OPGs is vital to therapeutic progress in this field. This chapter will briefly review the epidemiology, presentation and management of NF1-associated OPGs. It will also discuss the current outcome measures for OPGs and review potential OPG surrogate endpoints that may help determine or predict vision loss in children with these tumors.

EPIDEMIOLOGY OF OPGS

OPGs most commonly arise in young children, with a median age at diagnosis of 4.9 years. [3, 10] Although it is unusual for new symptoms to emerge after 6 years of age, [4] it is now clear that older children and adults may also develop symptomatic OPGs. [11] Some studies report an increased incidence in females; [3, 12] however, others show the ratio of females to males to be equal. [5, 13-15] Most tumors involve the anterior visual pathways, including optic nerves and chiasm, [3] but approximately 50% also involve the posterior visual pathways, including optic tracts and radiations. [7] Although estimates of the incidence of NF1 among patients with OPGs varies widely, [13, 16] one large, single-institution study suggests that up to 58% of OPGs are found in children with NF1. [17]

PRESENTATION OF OPGs

Clinical Symptoms

OPGs may or may not be symptomatic at diagnosis. Asymptomatic tumors may be identified during routine ophthalmologic screening (e.g., optic pallor), during an MRI evaluation of the brain for another reason, or at institutions where MRI's are performed routinely as part of an NF1 screening protocol. It is unclear what proportion of NF1 children diagnosed without visual deficits are actually treated pre-symptomatically and how this strategy affects visual outcomes.

Symptomatic OPGs often present with vision loss, although young children with symptomatic tumors rarely complain of decreased acuity. [6, 18] Other signs and symptoms can include headache, ocular misalignment (strabismus), nystagmus, and proptosis. Precocious puberty can occur when the tumor involves the hypothalamus. [5, 19]

Diagnostic Imaging

The diagnosis of OPG is made primarily from MR imaging of the brain and orbits, preferably with thin slices through the optic nerve and chiasm. Biopsy is not necessary for lesions with characteristic clinical and imaging features, particularly in patients with NF1, and is reserved for unusual presentations in which the diagnosis is in doubt. [20] MRI is also the standard modality for surveillance of known tumors.

Figure 1. (A) Coronal T2-weighted MRI demonstrating an optic chiasm glioma. (B) Axial postgadolinium T1-weighted MRI of an optic nerve glioma.

OPGs generally appear isointense on T1-weighted sequences and iso- to hyperintense on T2-weighted sequences (Figure 1). Enhancement with gadolinium is common, but is more frequently seen in sporadic rather than NF1-associated OPGs. [21] Tumors of the optic nerve

may be fusiform, and kinking may cause a downward turn of the intraorbital segment of the optic nerve. [22] Although commonly seen in OPGs, nerve tortuosity alone is not sufficient for a diagnosis of an optic nerve glioma. [23] Dilatation of the subarachnoid sleeve surrounding the optic nerve can cause expansion of the dural sheath, although this "dural ectasis" may be more a developmental than a neoplastic manifestation in NF1 patients. Bilateral optic nerve tumors are almost exclusively seen in NF1-associated OPGs. Tumors of the posterior optic pathway may be diffuse, bilateral and without clear borders; they are most apparent on T2 sequences with variable degrees of enhancement. [21, 24]

PATHOLOGY

Optic pathway gliomas are histopathologically low-grade gliomas, typically pilocytic astrocytomas (WHO grade I), although other low-grade glioma variants are reported as well, [25-27] and NF1-associated and sporadic versions are histologically identical. [1] Microscopically, these tumors are composed of glial fibrillary acidic protein (GFAP) staining astrocytes, often with characteristic Rosenthal fibers. Tumors may lack these characteristic findings and be classified as fibrillary (WHO grade II) tumors; however, tumor grade has not been correlated with tumor progression or behavior. [28, 29]

MANAGEMENT OF OPGs

Clinical Course

Although OPGs are generally slow growing, [5, 15] individual tumors can show extreme variability in growth velocity. Some may have long periods of quiescence, followed by periods of rapid symptomatic growth. Occasional cases of spontaneous tumor regression have also been reported. [30-36] Unfortunately, improvement in MRI abnormalities does not always correlate with visual improvement in children. [30]

Multiple studies have investigated potential prognostic factors for NF1-associated OPG growth or vision loss. Anterior location of the OPG is associated with less aggressive behavior in some series, [7, 37] but not all. [5] Age (<2 years or >5years) has been associated with worse outcomes in some series. [8, 38, 39] Histology has not been shown to predict OPG behavior. [28, 29] In one of the largest studies, characteristics at presentation were investigated as prognostic factors for eventual treatment need in 90 children with NF1-associated OPG (51 symptomatic and 29 asymptomatic); [5] no factor (including tumor location, age at diagnosis, presenting symptoms, NF1 symptoms, or associated features) was found to be prognostic. Since there is currently no reliable indicator to predict future vision loss in OPGs, identifying visual deficits early may be the most important factor in preserving vision.

Surveillance

Child-reported vision loss is an unreliable marker of a symptomatic OPG, since young children rarely complain of vision loss. [6] Instead, children with NF1 should have annual comprehensive ophthalmologic evaluations by a pediatric ophthalmologist or neuro-ophthalmologist familiar with NF1. Although many guidelines recommend annual eye exams until 7 years of age, [6, 40] monitoring every other year should continue into adulthood given that some older children may remain at risk. [11] Comprehensive ophthalmology evaluations should include monocular visual acuity testing appropriate for the patient's age and cognitive abilities (e.g., Teller Acuity Cards, HOTV, Lea figures or Snellen, see Table 1), [9] an assessment of visual fields, color vision, and pupillary responses, and fundus examination to evaluate the optic discs.

Once symptoms or abnormal findings are identified on ophthalmologic evaluation, MRI of the brain and orbit should be used for diagnosis and localization. In general, MRI screening in asymptomatic individuals is not recommended because identification of asymptomatic OPGs does not affect visual or overall mortality outcomes. [4, 40] However, radiologic screening may be valuable if a patient is too young for a reliable ophthalmology examination. There is no clear consensus on imaging frequency once an OPG is identified, but expert reviews suggest MRI evaluations every three months for the first year after detection, with increasing intervals thereafter for stable lesions. [6]

Table 1. Age-based visual acuity testing and norms. Adapted from Listernick et al, *Ann Neurol* 2007;61:189-198

Age (years)	Recommended Testing Method	Normal Visual Acuity
0.5 – 2	Teller Acuity Test	age-based norms
3	Lea figure	20 / 40
4	HOTV matching	20 / 30
5	Snellen	20 / 25
≥6	Snellen	20 / 20

Treatment

Treatment is reserved for clinical and sometimes radiologic progression. Clinical progression consisting of a two-line decrease in visual acuity in one or both eyes on the Snellen, HOTV or Lea charts is suggested before considering treatment in an expert review,⁶ although a new visual field quadrant deficit may also prompt treatment. Caution should be applied, as determining a significant change in vision can be difficult since subject cooperation and age-defined normal acuities may vary between assessments. Many clinicians will also treat for progressive tumor growth on MRI, although radiographic growth has not necessarily correlated with progressive vision loss in multiple studies. [8, 41, 42]

Chemotherapy with carboplatin and vincristine is considered first-line treatment for NF1-associated OPGs. This regimen results in a 5-year progression free survival of 69% in children with NF1; [43] however, a high rate of allergic reactions to carboplatin led to discontinuation

of therapy in 19% of subjects. Unfortunately, for patients unable to receive carboplatin, there is no consensus of second-line treatment regimens in NF1-associated OPGs. The TPCV regimen (thioguanine, procarbazine, lomustine (CCNU) and vincristine) has equivalent efficacy to carboplatin/vincristine in subjects without NF1, [44] but this regimen is often avoided in patients with tumor predisposition syndromes such as NF1 due to the risk of second malignancy after exposure to the alkylators lomustine and procarbazine. [45] Cisplatin and etoposide have been successful in low grade gliomas, demonstrating a 3-year progression free survival of 73%, but etoposide has also been shown to increase the risk of secondary leukemia and cisplatin can cause hearing loss, which is of particular concern in patients with diminished vision. [46] Bevacizumab/irinotecan, [47] vinblastine, [48] and temozolomide [49] have also been used as second-line agents in recurrent and refractory OPGs; however temozolomide is also associated with an increased risk of developing secondary malignancy. Other agents currently under investigation in early clinical trials for NF1-associated OPGs include lenalidomide and everolimus. [50]

Despite their efficacy for tumor control, the morbidity associated with radiation therapy and surgical excision make them therapies of last resort for NF1-associated OPGs. Radiotherapy is associated with a 10-year progression free survival between 65 and 90%, [51-54] but is avoided due to the increased risk of second malignancy, [55] cerebrovascular disease, [56-58] endocrine complications [51, 52, 59] and neurocognitive deficits. [27, 54, 60] Although surgery is the mainstay of therapy for pediatric low-grade gliomas in the cerebellum and superficial cortex, resection of optic pathway gliomas can lead to further visual decline, as well as risks of endocrine and cerebrovascular complications. [45] Surgical resection may be indicated for unilateral optic nerve gliomas when vision has been lost and extensive proptosis results in corneal exposure. [6] Tumor debulking of hypothalamic tumors may also decompress hydrocephalus by removing tumor obstructing flow at the foramina of Monro. [6]

OUTCOME MEASURES

The past two decades have led to remarkable advances in our understanding of the natural history, biology and treatment of NF1-associated OPGs. Clinical trials have identified chemotherapy regimens that are safe and efficacious in preventing death or radiologic progression. Recently, however, the focus of clinical research in OPGs has shifted from preventing radiologic progression to avoiding progressive vision loss, since this is the ultimate goal of treatment. [9] Therefore, determining reliable and clinically meaningful endpoints for visual outcome is a vital part of future clinical trial design in OPGs. At this time, visual acuity is the best outcome measure for OPGs. However, surrogate endpoints and biomarkers for visual function in children with OPGs are nevertheless desirable for two major reasons: 1) some children may not cooperate sufficiently for reliable visual assessments, and 2) a test which might indicate impending vision loss before it occurs could guide treatment decisions and might preserve normal vision. Ideally, such novel surrogate markers would be generally available, minimally invasive, inexpensive, rapid and reliable. Most importantly, they need to correlate closely with visual function. In many cases, the development of potential surrogate markers is already underway. However, more study will be necessary to validate these methods prospectively before they may be useful for the clinical management of OPGs.

Anatomical Outcomes (MRI)

Because an OPG is rarely fatal, [43] most clinical trials evaluate radiologic progression free survival or tumor response to determine treatment efficacy. [61-63] Modern MRI techniques with thin slices, high resolution and gadolinium contrast agents have been a boon to the diagnosis, localization and assessment of OPGs. MRI can measure tumor volume and detect tumor growth reliably, reproducibly, and independent of patient factors such as cooperation or attention. However, traditional measures of imaging response (complete response, partial response, stable disease and progressive disease) may be difficult to measure accurately in children with NF1 who often have changing areas of benign T2-weighted hyperintensity (unidentified bright spots) and variable degrees of enhancement in the optic pathways. In addition, many children require sedation for their MRI to be completed.

Routine MRI screening in visually asymptomatic children with NF1 has been evaluated in a handful of screening programs and has not been shown to predict visual outcomes. In a review of 32 children with NF1 who were referred but not initially treated for an OPG, there was no difference in radiologic signs between patients who clinically progressed and those that did not. [64] Although contrast-enhancement is cited by some as a factor influencing a clinician's decision to treat OPGs, [8] other large studies have not found an association between enhancement and prognosis. [24] In addition, dynamic changes in MRI may not correspond with clinical changes. Retrospective studies demonstrate examples of children where change in enhancement or tumor size on MRI did not correlate with clinical outcomes. [21, 65]

As a surrogate marker in clinical trials, MRI is unable to differentiate important functional outcomes, and traditional measures of imaging response do not correspond with visual outcomes. Campagna et al. [66] in 32 children with sporadic OPG found a poor correlation (59.4%) between visual acuity and radiologic outcomes. Increased tumor volume did seem to be associated with worse visual acuity (corresponding in 10 of 11 cases with increased tumor volume), but a substantial proportion of patients with worse visual acuity were not identified by tumor progression (9 of 19 patients with worse visual acuity had either stable (n=1) or reduced (n=8) tumor volume). Shofty confirmed this trend in 19 patients who received chemotherapy for OPGs. [67] Overall, MRI changes corresponded to visual changes in 52.6%. Again, children with radiologic progression predominantly had worse visual outcomes (8 of 11 children with tumor progression also had worse visual outcomes), but children with worse visual outcomes did not consistently have tumor progression (57% progression, 21% stable, and 21% improved tumor size). Fisher et al. performed the largest study on visual outcomes in children treated for NF1 associated OPGs. [8] Their study found that visual and imaging outcomes corresponded only in 38% of the 71 children with both radiologic and visual outcome data. In that study, only 3 of 22 children with a decline in visual acuity had radiologic progression. Although it seems that children with progressive disease after therapy may have an increased risk of worse visual outcomes, it is clear that tumor progression on MRI is a poor surrogate for visual acuity as an outcome measure in children treated for OPGs.

Visual Outcomes

Change in visual acuity is one of the most important factors guiding treatment decisions in OPGs. [6, 8] While the impact of childhood-onset vision loss has never been systematically

investigated in children with OPGs, vision loss in adults affects quality of life, educational level, income and self-perception. In a study of adult vision loss from a 1958 British birth cohort, Rahi and colleagues found that all-cause visual impairment was associated with increased odds of unemployment, lower socioeconomic status and worse mental health. [68] Likewise, in a study from the 1995 National Health Interview Survey on Disability, Swanson et al. demonstrated that severe vision impairment and legal blindness were associated with difficulties in activities of daily living (ADLs) and instrumental activities of daily living (IADLs). [69] In a stratified analysis, the effect of vision on ADL/IADL function was modified by age: vision impairment and blindness produced a graded effect, with the greatest impact among the youngest subjects. For instance, the odds ratio for difficulty with eating was 6.18 (95% CI 2.52–15.17) in subjects 18–44 years old with severe visual impairment, but only 1.23 (95% CI 0.75–2.01) among subjects ≥ 65 years of age.

Visual acuity is the most important functional outcome measure in clinical trials of OPG. Unlike radiologic progression which may be clinically asymptomatic, vision loss is a significant and clinically meaningful consequence of OPG progression. Although there are other clinically meaningful complications associated with OPG (i.e., endocrinologic or neurologic), loss of visual acuity is by far the most frequent and therefore the most commonly used functional outcome measure. Among visual parameters, visual acuity is the most easily obtainable, reliable, and reproducible, even in young children, [6, 9] and the intervals for improvement or worsening (lines or logMAR – see below) are easily understandable. Other vision-related abnormalities, such as visual field defects, color vision deficits, strabismus, or nystagmus rarely occur without associated visual acuity loss in OPGs, and optic atrophy can occur without vision loss. For these reasons, and because these other features are not as reliably measured, they are less desirable than visual acuity as outcome measures for OPGs.

Comparing visual acuity longitudinally or between groups can be challenging. Vision testing relies on patient cooperation and attention, and patient factors such as fatigue due to therapy may impact test results and reliability. Learning differences and attention deficit/hyperactivity disorder are common among children with NF1 [70] and might further complicate vision testing. Children with NF1 who are unable or unwilling to complete a comprehensive ophthalmologic examination should return for repeat testing within a week or two. In addition, a review of ophthalmologic screening in 37 children followed at a single center showed that only 43% received the recommended annual ophthalmologic screening from diagnosis until seven years old. [71] Visual acuity assessments were completed successfully in all patients, but 35 of 37 (95%) of subjects were deemed too immature to undergo color vision and visual field testing.

Age-based visual acuity testing can also affect the comparability of visual outcomes. Appropriate visual acuity assessments depend on the age and developmental abilities of each child. While preferential looking tests such as Teller Acuity Cards may be used in very young and pre-verbal children, [72] older children will be able to match symbols (Lea figures) or letters (HOTV) and eventually identify letters (Snellen). While these tests all reflect visual acuity, they may not be entirely comparable. Teller Acuity Cards are a test of preferential looking, while tests in older children require recognition of the symbol and letter. These tests may under- or over-estimate visual acuity in different acuity ranges. [73, 74] The complexity of the test may also affect the results. Lea figure testing and HOTV testing each present four possible choices, giving a 25% chance of guessing each correctly, while Snellen charts use twenty or more different letter options. [9] As children age and develop, they are able to

complete more rigorous visual acuity testing. However, it is unclear how transitions among tests for visual acuity may affect reported outcomes. Further, children with NF1 may be developmentally behind their age-matched peers and, therefore, may not be able to complete the same testing as non-NF1 control subjects at an equivalent age. For this reason, it has been suggested that future clinical trials in NF1-associated OPG mandate the use of identical testing methods (Teller acuity cards or HOTV) throughout longitudinal analysis. [9]

Many older studies use a two-line decline in visual acuity measured on a Snellen chart as a significant change in vision. However, gradations in the traditional Snellen chart are not linear, thus the magnitude of a two-line decline in vision is greater when a patient's baseline is 20/70 (to 20/200) than when it is 20/25 (to 20/40). This can complicate both inter- and intra-testing comparisons. To convert the Snellen gradations to a linear scale, many researchers have used the logarithm of the minimum angle of resolution ($\log\text{MAR}$ = base 10 logarithm of (1/Snellen decimal equivalent)). For example, if the Snellen visual acuity is 20/40, the decimal equivalent is 20 divided by 40 = 0.5, and therefore the $\log\text{MAR}$ equivalent of 20/40 is $\log_{10}(1/0.5) = 0.3$). While the meaning of a single visual acuity reading in $\log\text{MAR}$ may be less intuitively obvious than Snellen readings, the change in vision can be compared across the range of visual deficits. It is generally agreed that a change in visual acuity of 0.2 $\log\text{MAR}$ is clinically significant.

ALTERNATIVE OUTCOME MEASURES

Because of the varied penetrance, clinical course and timing of OPGs and their complications, there has been increasing interest in non-invasive measures as surrogate markers for important endpoints and to predict complications that might influence patient care or quality of life. The development of inexpensive outcome measures to predict vision loss in NF1-associated OPGs is especially important and may help steer potential treatment decisions or improve monitoring of treatment effect.

However, the development of surrogate endpoints faces many challenges. OPG remains a rare tumor, and tumors that merit treatment are even less common. In addition, conventional molecular markers and immunohistochemical stains developed for low-grade gliomas are of limited value in OPGs. These markers require surgical biopsy, which is often avoided due to significant morbidity and is unnecessary in the setting of classical radiologic findings. Instead, interest in OPG surrogate endpoints has turned to alternative imaging and electrophysiologic modalities (Table 2).

Diffusion and Perfusion Imaging

Diffusion Weighted Imaging (DWI) and Apparent Diffusion Coefficient (ADC) maps measure the relative diffusion of water in each voxel of an MR image. Dynamic Contrast-Enhanced (DCE) imaging repeats sequences of images during the infusion of a contrast agent to measure the permeability of a lesion. Both have been useful in the evaluation of brain tumors. Diffusion imaging has been shown to distinguish low- versus high-grade gliomas in adults [75, 76] and differentiate enhancing pilocytic astrocytomas from higher-grade gliomas. [75] DCE

MRI has been useful in identifying glioma grade and assessing their microvasculature and heterogeneity. [77] Recent studies suggest that diffusion imaging may predict brain tumor response to therapy at an early stage, providing an early non-invasive indicator of treatment efficacy. [78, 79]

Table 2. Surrogate Markers of Vision*

Author, Year	Reference	OPGs / NF1-associated OPGs	Results	Comments
Diffusion/Perfusion Imaging				
Jost, 2008	84	27 / 14	Permeability was greater in tumors that had required treatment	No difference in diffusion-weighted imaging
Diffusion Tensor Imaging (DTI)				
Lober, 2012	87	10 / 4	Visual pathway fiber attenuation was seen in all OPGs	No correlation between visual acuity and fiber attenuation
Filippi, 2012	98	53 / 9	DTI measurements were different in NF1 vs normal controls	A correlation between vision and DTI was not measured
de Blank, 2013	138	50 / 50	Visual acuity deficits correlated with changes in white matter integrity	
Positron Emission Tomography (PET)				
Moharir, 2010	108	9 / 9	Sensitivity 62.5% and specificity 87.5% to detect symptomatic OPG	Unable to predict tumors that will need therapy
Molloy, 1999	107	24 / 24	Increased FDG uptake correlated with tumor behavior (stable vs progressive) in 96%.	Only published as an abstract
Visual Evoked Potentials (VEPs)				
Ng, 2001	124	10 / 8	50% correlation between change in VEP and change in visual acuity	VEP changes corresponded to change in MRI in 7 of 10 subjects
Trisciuzzi, 2004	125	18 / 5	VEP amplitude correlated with visual acuity deficits	12 of 18 had partial surgical excision of tumor
Kelly, 2012	130	21 / 6	Change in VEP amplitude did not correlate with change in visual acuity after treatment	
Wolsey, 2006	128	14 / 14	Sensitivity of 86% and specificity of 75% to detect symptomatic or asymptomatic OPGs	Normalization of VEP and improvement in vision after radiation in one subject.
Falsini, 2008	129	14 / 4	Change in flicker VEP testing corresponded to visual acuity changes 58% of the time.	
Optical Coherence Tomography				
Avery, 2011	26	48 / 34	Retinal Nerve Fiber Layer thickness associated with visual acuity	Prospective study ongoing

*includes only reports with more than 5 subjects that compare surrogate measures to visual outcomes.

Studies of these techniques in children and in optic pathway gliomas are limited. Lope et al. [80] examined the utility of DWI in the identification of pediatric orbital tumors. The single OPG in this sample was too small for an adequate reading of diffusivity. Sener studied a case of a one year-old child with NF1 and a chiasmatic OPG. [81] ADC values were compared with 12 control children (aged 9 month to 3 years). The ADC of the chiasmatic OPG was not

different from that of normal white matter in controls ($0.81 \times 10^{-3} \text{ mm}^2/\text{s}$ vs. $0.84 \pm 0.14 \times 10^{-3} \text{ mm}^2/\text{s}$).

Jost et al. provide the only large study of diffusion and perfusion imaging in children with OPGs. [82] They performed a cross-sectional study of 27 children with OPGs (14 with NF1) with diffusion weighted and DCE MRI protocols. Mean diffusivity values on ADC were no different between OPGs requiring and not needing treatment; however, mean permeability measured by DCE MRI was greater in more aggressive ($2.24 \text{ mL/min per } 100 \text{ cm}^3$) compared to clinically stable tumors ($1.38 \text{ mL/min per } 100 \text{ cm}^3$, $p=0.05$). Forty-seven percent of aggressive tumors but no stable tumors had permeability greater than $2 \text{ mL/min per } 100 \text{ cm}^3$, suggesting that this may be a useful threshold to identify a subset of those tumors requiring closer monitoring or treatment. A larger sample of NF1 associated OPGs will need to be studied in a longitudinal framework in order to determine if permeability correlates with progressive disease over time.

Diffusion Tensor Imaging

Diffusion Tensor Imaging (DTI) allows identification and quantitation of white matter tracts including optic nerves, tracts and radiations. DTI measures the diffusion of water molecules as they move preferentially along, as opposed to across, white matter fibers. By measuring the predominant direction of water diffusion in each voxel, a map of white matter tracts can be created. DTI can thus localize and quantify the relative number and density of selected white matter tracts (see Figure 2). By measuring the proportion of diffusion that occurs in a single direction (fractional anisotropy, FA) and the mean squared diffusion of water in three perpendicular directions (mean diffusivity, MD), [83] DTI can also examine the integrity of white matter tracts.

Figure 2. Visual pathway tracts from diffusion tensor imaging superimposed on axial and sagittal views of the brain. Optic nerves (green), optic tracts (red) and optic radiations (blue) are depicted.

Tract localization using DTI has been used to help guide surgical resection to avoid optic radiations, [84, 85] and measures of white matter integrity have predicted histological grade in cerebral gliomas. [86-88] In addition, DTI of the optic nerve was performed in a mouse model of NF1-associated OPG. In that model, DTI measurements showed that white matter integrity was decreased in gliomatous optic nerves, and integrity continued to decrease over time. [89]

However, there are inherent difficulties with measuring a diffusion tensor in the optic nerve. The nerves are small, subject to motion with eye movement and surrounded by intraconal fat, bone and air in the adjacent sinuses that can cause susceptibility artifact. [90-92] Further, measurements of the diffusion tensor in the optic chiasm are prone to error due to the decussation of white matter tracts. [93, 94] Despite these difficulties, Nickerson et al. were able to measure the diffusion tensor of the optic nerve in 5 children with intrinsic optic nerve pathology (septo-optic dysplasia and optic glioma), four children with extrinsic optic nerve compression (from craniopharyngioma, hypothalamic germinoma, and pilomyxoid astrocytoma), and 70 healthy pediatric controls. [95] Intrinsic lesions (including OPGs) had significantly different measures of white matter integrity (FA and MD) than either extrinsic lesions or healthy controls. Unfortunately, OPGs were not studied independent of other intrinsic lesions, and neither NF1 status nor vision was reported. In a follow-up study, the investigators performed DTI of the optic nerve and optic radiations in 9 children with NF1 (5 with OPGs) and 44 healthy age-matched controls. [96] Although OPGs were limited to the optic nerves and chiasm, children with NF1 had significantly different FA and MD measurements than healthy controls in both optic nerves and optic radiations. It is unclear whether the difference in FA and MD found in children with NF1 is due to their NF1 status or the presence of OPGs, and a lack of reported vision testing makes it impossible to relate changes in DTI parameters to visual deficits in these children.

A comparison of visual outcomes with the quantity of visual fibers in 10 children with OPGs (four with NF1) found attenuated or absent visual fibers in all subjects, but no statistically significant association could be found with abnormal visual acuity. [85] Of interest, optic radiation fibers were diminished or absent in nine of 10 children, although none had optic radiation involvement of their OPG. The deficit in posterior fibers may be due to anterograde transsynaptic degeneration from disruption of visual input, [85, 97] or perhaps indicates that DTI is more sensitive to tumor involvement in the posterior radiations than MRI.

To determine if DTI may be an appropriate endpoint for vision loss in NF1-associated OPG, our group investigated 50 children with NF1-OPG who had both a comprehensive ophthalmic examination and DTI of brain and orbits within three months of each other. [138] Multivariate analysis suggests children with abnormal visual acuity had significantly worse measures of white matter integrity (FA and MD) in the optic radiations. This difference persisted after controlling for age and tumor location, as well as in a subanalysis of subjects without tumor involvement of the radiations.

DTI offers many advantages as a potential surrogate marker of visual acuity in OPG. It is acquired with traditional MRI, and so is both non-invasive and convenient. It is also cost-effective as an “add-on” sequence if MRI is already being performed. Unlike many potential surrogate endpoints that are difficult to perform in young children, DTI can be performed at almost any age, although age-based norms for DTI measurements should be determined before wide use can be recommended. DTI can also characterize structural deficits of the posterior optic pathway, and might in the future be investigated in conjunction with optical coherence tomography (which examines the anterior pathway) to determine if these tests may predict vision loss better in combination.

For DTI to become a useful surrogate endpoint for vision loss in OPG there are several limitations to address. First, DTI measurements show a significant variability that may limit their usefulness to individuals rather than populations. Second, measurements of pre-geniculate structures (optic nerve, chiasm and tract) are technically difficult, increasing the variability of

DTI measurements in these regions. Finally, the impact of unidentified bright objects, commonly seen in the brains of NF1 patients, should be investigated to determine if these asymptomatic structures confound the relationship between DTI measurements and visual outcomes. Ultimately, longitudinal studies in larger NF1 populations are needed to determine if DTI changes predict or are provoked by vision loss.

Positron Emission Tomography

Positron emission tomography (PET) has been investigated as an alternate imaging modality for the evaluation of OPGs in NF1. PET imaging depends on a positron-emitting radionuclide tracer attached to a biologically active molecule that is introduced into the subject's body. Tracer concentration can be imaged in three dimensions and provide information on a variety of metabolic processes. The most common tracer used is [18F] fluorodeoxyglucose (FDG), which has a relatively long half-life (approximately 110 minutes) and can be used to detect levels of glucose metabolism throughout the body.

FDG-PET imaging has already proven its usefulness in patients with NF1 to help differentiate benign neurofibromas from malignant peripheral nerve sheath tumors. [98-101] In addition, the utility of PET for the clinical management of adult brain tumors, particularly for tumor detection, defining tumor extent and treatment planning is established. [102] There is relatively less information on PET in the evaluation of pediatric brain tumors. In a survey of physicians who ordered PET imaging for a child with a CNS tumor, PET was deemed to be helpful in 48 of 59 (77%) cases, but changed management in only 9 (15%). [103]

Small studies and case series suggest that PET imaging may be useful in characterizing the growth potential in OPGs. Increased FDG was reported to be useful in clinical decision-making in an adult with an OPG. [104] In a larger study describing 24 patients with NF1 and low grade gliomas of the optic pathway, thalamus or brainstem, there was a 96% correlation between tumor FDG uptake and disease status. [105] In that study, all seven subjects with progressive disease had increased FDG uptake, while 16 of 17 with stable disease had no increased uptake; however, only an abstract of this work has been published.

In a retrospective report of 16 OPGs among nine children with NF1, five of eight symptomatic tumors (four with disc pallor, three with visual impairment and one with proptosis) had abnormal FDG uptake (standardized uptake value (SUV) >3), in contrast to only one of eight asymptomatic OPGs. [106] The diagnostic sensitivity and specificity of FDG PET for identifying symptomatic tumors was 62.5% and 87.5%, respectively. Overall, FDG-PET does not appear to have the sensitivity necessary to be a useful tool in identifying symptomatic OPGs in children too young to sufficiently cooperate with ophthalmologic testing. Further, on longitudinal evaluations, FDG-PET was unable to predict which tumors would subsequently need treatment. However, two subjects with elevated SUV at baseline had an improvement in symptoms and a reduction in SUV uptake following chemotherapy.

Other case reports of PET imaging for OPGs have used alternative tracer molecules, such as alpha-[11C]methyl-L-tryptophan (AMT) [107] and [18F]fluorocholine. [108] These molecules provide better contrast between tumor tissue and surrounding healthy brain. [109, 110] However, the short half-life of AMT requires on-site production with a cyclotron, limiting its general utility. Larger studies of these alternative tracer molecules will be necessary before their potential utility in following OPGs can be determined.

PET imaging can help differentiate malignant from non-neoplastic tissue and orient therapeutic management in pediatric brain tumors, [111] but it has not yet proven its usefulness in OPGs. While new tracers may lead to increased sensitivity in detecting symptomatic OPGs, they have not been able to predict vision loss or aggressive behavior in an OPG. Further, the short half-life of many radionuclides limits their utility in many centers without an on-site cyclotron. Despite anecdotal examples of FDG uptake in OPGs, [112] FDG-PET is not sensitive to symptomatic OPGs and longitudinal evaluation has only been shown to correlate with chemotherapy response in select cases. Further, PET has innate disadvantages in the NF1 population, where unnecessary radiation should be avoided because of significant risks of second malignancies [55, 113] and cerebrovascular complications. [56, 57] While PET imaging has many uses in childhood brain tumors, radionuclide development and further investigations are necessary before PET can be useful as an endpoint in OPGs.

Visual Evoked Potentials

Visual evoked potentials (VEPs) measure cortical activity in response to visual stimuli. Electrodes are placed on the scalp in the occipital region (similar to those used for electroencephalography) and patients are shown a variety of patterns or lights to provoke electrical activity in the visual cortex. Resulting electrical potentials can be plotted against time to give information about the visual circuits from retina to occipital cortex. Decreases in amplitude or delays in evoked responses (latency) may signal damage to those circuits. VEPs are noninvasive and require no anesthesia. Thus, VEPs have been proposed as a method to detect the presence of an OPG and to monitor for vision loss.

Initial investigations with VEPs in OPG in 1983 showed that VEPs were abnormal or absent in seven children with proven or putative OPG. [114] Subsequent studies suggest that VEP can identify OPGs with a sensitivity between 90% [115] and 100% [116, 117] and specificity of 60% [115] to 69%, [117] although other studies of NF1-associated OPG revealed normal latency and amplitude. [118] Traditional VEP tests use an alternating, high-contrast checkerboard pattern. Alternative visual stimuli, including flash VEP (using rapid flashes of LED lights) and sweep VEP (using varying pattern size and contrast), resulted in decreased sensitivity but allowed younger children to be tested because less cooperation and concentration was required. [119, 120]

Although VEP testing has been shown to predict the presence of an OPG, many of the identified tumors were clinically silent. [116] Because the growth of OPGs is so variable, the utility of identifying asymptomatic OPGs is unclear. It is uncertain whether VEP can predict or identify symptomatic OPGs that require treatment. [121] Ng et al. [122] attempted to address this concern in a retrospective cohort of OPGs who had received repeated VEP, MRI and ophthalmology evaluations. In seven of ten subjects, VEP results over time corresponded with MRI results; however, a change in MRI corresponded to a change in VEP in only two of five paired evaluations. In addition, VEP corresponded with visual acuity only 50% of the time. In sum, VEP was not able to sensitively predict MRI or visual acuity changes.

VEP has been associated with visual acuity loss and visual field deficits in small studies of children with OPG. In 18 subjects with OPG and 16 age-matched controls, VEP results were correlated with visual acuity. [123] However, two-thirds of OPG patients had undergone tumor debulking, suggesting that abnormal VEP in this study may be identifying post-surgical tract

damage rather than the vision loss associated with this damage. In 15 subjects with OPG and 12 age-matched controls, Kelly et al. [124] showed that visual field loss was associated with decreased VEP amplitude. However, perimetry was not performed in the control group, and the OPG group had five subjects with NF1, while there were none in the control group. Previous studies [125] have shown that individuals with NF1 without OPG have abnormal VEP testing, suggesting the possibility of a primary abnormality of visual circuits in NF1. Therefore, it is important to control for NF1 status when evaluating VEP results.

To avoid this potential confounder, Wolsey et al. studied a retrospective cohort of 30 children with NF1 (14 with optic nerve glioma and 16 without OPG) who had undergone MRI and VEP evaluation. [126] VEP abnormalities identified optic nerve glioma with a sensitivity of 86% and specificity of 75%. Four individuals had serial VEPs and MRIs. In one subject, VEP abnormalities lagged behind MRI findings. In contrast, in two subjects, VEP abnormalities preceded MRI evidence of OPG. The last individual had normalization in VEP latency after radiation for an OPG that correlated with a decreased size on MRI and improved vision. These serial measurements suggest that VEP may be able to predict changes in MRI and may be useful in following vision after treatment in some patients.

Two recent longitudinal studies attempted to further examine the utility of VEP for monitoring children with OPGs. Falsini et al. [127] followed 14 children with OPG (four with NF1) with serial neuro-ophthalmic, MRI and flicker VEP evaluations roughly annually for a median of 3 years (range 6-76 months). Both serial flicker VEP ($K=0.67$, $p<0.001$) and visual acuity ($K=0.54$, $p<0.001$) correlated with serial MRI results 79% of the time. However, serial flicker VEP evaluations only agreed with serial visual acuity tests 58% of the time. Although both flicker VEP and visual acuity correlate with changes in MRI, visual acuity has the advantage of being a clinically relevant endpoint that might influence treatment decisions. Kelly et al. [128] recently reviewed 21 subjects (6 with NF1) aged 0.7 to nine years with bilateral OPG treated with chemotherapy, radiation or both. All subjects underwent VEP testing prior to treatment, during treatment and one to two years after treatment. Although latency was variable, all subjects had reduced amplitude in both eyes prior to treatment. Serial VEP testing showed no change in VEP amplitude between pre-treatment, during treatment or post-treatment time periods ($p>0.19$), and there was no relationship between VEP amplitude and response to treatment ($p=0.5$).

In summary, although VEP testing has been shown to be able to identify OPGs with some sensitivity, it has not yet been able to identify those tumors that require treatment, correlate with changing visual acuity or predict vision loss over time. Therefore, despite its theoretical potential as a fast and non-invasive method of interrogating visual circuits in OPG, it has not fulfilled this potential as a clinically relevant biomarker. Because of the wide variability in clinical behavior of OPGs, a clinically relevant biomarker must be able to predict or identify visual acuity loss or radiologic progression in order to affect treatment decisions.

Optical Coherence Tomography

Optical Coherence Tomography (OCT) of the retinal nerve fiber layer (RNFL) offers potential as a surrogate endpoint and biomarker of vision loss in NF1 associated OPGs. OCT relies on echo time delay of back-scattered infrared light to create a cross-sectional image of the retinal nerve fiber layer. The modality is analogous to ultrasound, but provides much better

resolution (approximately 3 micrometers). [129] OCT measurements of RNFL correspond with recovery of visual acuity and visual fields following resection of other tumors compressing the chiasm. [130, 131] In addition, OCT has been extensively investigated in multiple sclerosis and optic neuritis. Thinning of the RNFL on OCT is associated with visual field deficits in both cross-sectional [132] and longitudinal [133] analyses of subjects with a history of optic neuritis. Additionally, visual acuity, visual field and color vision deficits are associated with thinning of the RNFL in subjects with incompletely recovered optic neuritis. RNFL thinning is associated with visual acuity loss in patients with multiple sclerosis (without recent optic neuritis), [134] and OCT has been proposed as a surrogate endpoint and biomarker in multiple sclerosis.[135]

As OCT allows a rapid and inexpensive method of correlating structure and function, it may offer many advantages as a potential surrogate endpoint in OPGs. OCT may combine visual deficits in acuity, perimetry and color vision into a single structural endpoint. It requires less patient cooperation and is unaffected by patient fatigue. Although it may be difficult to perform in some young children, [136] portable devices are allowing investigators to measure RNFL during sedation.

Two investigations have examined the use of OCT in subjects with OPG. Chang et al. evaluated the RNFL of 15 subjects with NF1, nine with and six without an OPG. RNFL was significantly thinner (61.1 micrometers vs. 97.9 micrometers, $p=0.0001$) in subjects with OPGs. [137] However, visual deficits were not compared directly to OCT results in this study. Closer analysis reveals that seven of nine children with OPG had visual acuity equal or worse than 20/30, and all children without OPG had vision equal or better than 20/25, [136] suggesting that RNFL may not be simply a marker of OPG, but rather OPG with vision loss.

Avery et al. evaluated the association between RNFL thickness and visual deficits among 48 subjects with OPG (with and without NF1), 14 subjects with NF1 without OPG, and 14 healthy controls at least six years of age. [23] Among subjects with OPG, thin RNFL was associated with decreased high contrast visual acuity and low-contrast letter acuity when accounting for age and tumor location. Although a high degree of variability was seen in RNFL measurements, normal RNFL thickness was strongly associated with normal visual acuity and visual fields. The study did not perform a separate analysis restricted to NF1 subjects, but it did show that there was no significant difference in RNFL thickness between NF1 subjects without OPGs and healthy controls.

OCT measurement of RNFL holds promise as a potential surrogate endpoint for vision loss in children with OPGs. However, the correlation between RNFL thickness and visual acuity will have to be replicated in children less than 6 years, who are at the greatest risk for vision loss. Smaller, faster portable machines may make reliable measurements of RNFL in younger subjects possible, and studies of this age group are underway. Measurements of RNFL demonstrate significant variability, and larger populations should be studied to demonstrate the sensitivity and specificity of identifying vision loss with OCT. In addition, studies of OCT in optic neuritis reveal that significant changes in RNFL thickness lagged 4-6 months behind vision changes. [133] If this holds true for OPGs, OCT may not be able to predict acute vision loss, which is important for treatment decisions. Longitudinal studies currently enrolling children with NF1 as young as 18 months may help answer this question.

CONCLUSION

Currently, visual acuity is the most consistent and comparable measure of visual function aiding the management of children with NF1-associated OPG. However, the development of surrogate endpoints for vision loss offers the potential for reliable non-invasive tests that may work side by side with comprehensive ophthalmologic evaluations. Ideally, these potential biomarkers may also help predict subsequent vision loss and response to chemotherapy in this group that shows such enormous clinical variability. However, further research will be necessary before any of these novel potential surrogate markers are ready to help guide clinical management and decision-making in NF1-associated OPGs.

Chapter 111

NEUROFIBROMATOSIS TYPE 1 BONE DISEASE: DIAGNOSIS AND MANAGEMENT

Elizabeth K. Schorry¹ and Alvin H. Crawford²

¹Division of Human Genetics, Children's

Hospital Medical Center, Cincinnati, OH, US

²Department of Pediatric Orthopaedics, Children's

Hospital Medical Center, Cincinnati, OH, US

ABSTRACT

Osseous abnormalities occur frequently in NF1, and can present in a multitude of ways. Bone disorders in NF1 can be categorized as generalized or focal. Generalized bone involvement occurs frequently to a mild degree, and can include short stature, macrocephaly, and osteopenia. Focal, dystrophic features such as tibial dysplasia/pseudarthrosis and dystrophic scoliosis are challenging to manage effectively. Additional features can include dural ectasia of the spine, sphenoid wing dysplasia, leg length inequality, pectus deformities of the chest, non-ossifying fibromas of long bones, and ossifying subperiosteal hematoma. Early recognition of musculoskeletal complications is important in improving outcome.

INTRODUCTION

There is increasing evidence that a primary skeletal dysplasia exists in NF1. This concept was introduced by Dr. Vincent Riccardi in 1986 [1], and has received revived attention in more recent years. Osseous abnormalities occur in up to 38% of patients with NF1 [2], and can usually be categorized as either focal or generalized. Generalized skeletal manifestations, such as osteopenia, osteoporosis, and short stature are common in NF1 but usually mild [3]. Focal skeletal abnormalities include dystrophic scoliosis, sphenoid wing dysplasia, and tibial dysplasia/pseudarthrosis. These focal deficits are less common than the generalized ones, but can carry significant morbidity and treatment challenges.

Pectus deformities of the chest wall are also well known to be associated with NF1 and may represent an area of overlap between focal and generalized osseous manifestations.

The pathophysiology of bone manifestations in NF1 is not yet fully elucidated. Although some bone abnormalities may be secondary to presence of tumors and their effects on Nf1 haploinsufficient bone, others are more likely the result of a primary osseous dysplasia. The study of animal models and human tissues has provided significant insight into bone biology in NF1. While neurofibromin's role as a tumor suppressor is well known, it is becoming apparent that neurofibromin also plays a significant role in bone homeostasis, remodeling, and fracture healing.

Mouse models have demonstrated that neurofibromin plays a role in growth and differentiation of both osteoblasts and osteoclasts with decreased differentiation of osteoblasts and increased activity of osteoclasts seen with haploinsufficiency of neurofibromin [4]. These changes likely contribute to the bone dysplasia and abnormal healing of bone seen in NF1. Some of the focal complications of NF1, particularly tibial pseudarthrosis, have been found to involve bi-allelic inactivation of Nf1 in affected tissue [5, 6] and it is possible that other focal osseous complications may involve a similar second hit event.

SPINAL MANIFESTATIONS : SCOLIOSIS

Spinal deformity is the most common of the focal osseous complications of NF1, occurring in 10–30% of patients in NF clinic populations [7, 8]. In general NF clinic patients, the prevalence of scoliosis is about 15%; but a prevalence over 25% can be seen in clinics biased towards specialized orthopedic care (Schorry and Crawford, unpublished data). Both males and females with NF1 are equally likely to be affected with scoliosis, in contrast to the non-NF population where idiopathic scoliosis is much more common in females. Two distinct types of scoliosis curves can occur in NF1: a non-dystrophic curve similar to that seen in idiopathic scoliosis (Figure 1); and a dystrophic curve, which is highly likely to progress.

Figure 1. Non-dystrophic scoliosis. This 13 year old child presented with a 45 degree curve. No dystrophic features are present.

Figure 2. Dystrophic scoliosis. AP and lateral views of a 12 year old child with dystrophic scoliosis. This is a 60 degree focal left thoracic scoliosis. The hazy density above the apex of the curve seen on both the AP and lateral views was identified on MRI as a paraspinal plexiform neurofibroma.

Dystrophic curves (Figure 2) are characterized by a short-segmented, sharply angulated deformity, usually involving 6 or fewer vertebrae [9]. Additional dystrophic features on radiographs (Figure 3, 4) can be predictive of progression and need for future surgery and include: posterior and anterior vertebral scalloping, vertebral rotation, vertebral body wedging, rib “pencil” or rotation, spindling of transverse processes, widened interpediculate distance and enlarged intervertebral foramina [10].

Some of the dystrophic bony features are closely related to paraspinal or regional plexiform neurofibromas (Figure 5), and appear to be secondary to erosion by tumor growth; however, others can occur in the total absence of nearby tumors. Spinal deformities in NF1 can involve all areas of the vertebral column with thoracic and lumbar areas most commonly affected.

Cervical spine deformities, although less common, can result in cervical spinal instability and resultant neurologic compromise [2]. Kyphosis is commonly associated with the scoliotic curve. Spondylolisthesis, a pathologic subluxation of the lumbar vertebrae, is a rare complication. In a series of 131 patients with NF1 and scoliosis from Cincinnati Children’s Hospital, mean age at diagnosis of scoliosis was 9 years with 15% of patients having onset before age 7 years. Thirty-five (35)% required surgical correction, primarily anterior and posterior spinal fusion, and 63% had evidence of paraspinal tumors on imaging.

Need for surgery was equally distributed between males and females. Radiographic features highly predictive of subsequent need for surgery included vertebral scalloping, dural ectasia, presence of short-segmented focal curve and paraspinal tumors. However, presence of tumors was not a requirement for development of a severe dystrophic scoliotic curve (Schorry et al., manuscript in review).

Figure 3. Dystrophic elements. The predominant features of dystrophic vertebral bodies are: wedging in the frontal plane, scalloping or indentation of the cortex of greater than 3mm in the thoracic spine and greater than 4 mm in lumbar spine. Rib penciling is defined as the proximal third of the rib being thinner than that of the 2nd rib.

Figure 4. Proximal thoracic scoliosis. 3D reconstruction of the characteristic focal short segmented, sharply angulated proximal thoracic scoliosis, so often associated with dystrophic scoliosis.

Management of Scoliosis

Management of non-dystrophic curves should be similar to that used for idiopathic scoliosis. Generally, bracing should be considered for patients with curves between 25–40°; posterior spinal fusion for curves greater than 40°, and combined anterior and posterior fusion for curves greater than 55–60°. Dystrophic curves in NF1 represent a challenge for the spine surgeon. They are characterized by a rapidly progressive course, a tendency to evolve to a severe deformity, and a higher rate of pseudarthrosis after surgery.

Figure 5. Growing rods. Early onset scoliosis treated by Milwaukee brace and subsequent growing rods. The patient underwent a Risser case correction when the curve reached 50 degrees, and was corrected to 35 degrees and placed into a Milwaukee brace which subsequently failed. She was then treated by insertion of growing rods.

Typically, the goal of surgical management is to arrest the progression of deformity, rather than achieving complete correction. Almost all authors agree on an early and aggressive approach to dystrophic curves in NF1. Bracing has not been effective and is not recommended in any dystrophic deformity [11]. Dystrophic curves less than 20° should be monitored at 6 month intervals. For patients with curves between 20° and 40° , posterior spinal fusion is recommended, with use of autogenous iliac crest graft to minimize the occurrence of pseudarthrosis. For dystrophic curves greater than 40° or with kyphosis of greater than 50° , combined anterior and posterior spinal arthrodesis is recommended.

For very young patients less than 9 years of age with significant curve, placement of a growing rod (Figure 5) is an option. This technique requires fusing the cephalic and caudal anchors of the spinal rods which span the curvature and act as an internal brace. There is a tandem connector which allows for “growing”, lengthening the rods until skeletal maturity begins. Periodic lengthening of the spinal implants is required, usually at about 6 month intervals, followed by eventual definitive spinal fusion. It is a taxing process and although the child does not require a brace, the multiple procedures and potential and real complications cause it to be a less than ideal resolution of this problem. While trunk length may be of concern when performing a spinal fusion in young patients, the risk of plexiform tumors or dural ectasia eroding the bony vertebra justifies anterior and posterior fusion in severe dystrophic curves at a somewhat earlier age.

There is occasional modulation of a non-dystrophic curve to dystrophic, at which time it acquires the previously mentioned dystrophic characteristics. Data has shown that subtle dystrophic characteristics may have been present in this group of patients early on but could not be identified on plain x-rays [10].

Anterior and posterior spinal fusion is recommended for all dystrophic curves and every effort made to achieve this. On occasion the presence of plexiform neurofibromas or dural ectasia has eroded the vertebral body bone mass and pedicles to the point of not having sufficient fixation points for the instrumentation. In general, resection of paraspinal tumors encroaching on the spinal canal is recommended at the same time as spinal fusion, as tumor

resection without fusion can result in an unstable spine [9]. Complete resection of extensive paraspinal neurofibromas is generally neither feasible nor recommended.

After obtaining parental consent, we have occasionally used the growth factor, bone morphogenetic protein (BMP), off-label as an adjunct to achieve fusion. Postoperative brace-assisted immobilization is recommended after spinal fusion until a fusion mass is noted on imaging, in an effort to prevent pseudarthrosis.

Even though the strength of titanium, cobalt chromium and stainless steel is considerable, a failure of fusion of the vertebral bony mass will result in pseudarthrosis and ultimate rod breakage. Perioperative surgical complications include intraoperative hemorrhage, neuromonitoring alerts with or without paralysis.

Pseudarthrosis may occur but is usually noted after one to two years and more often by rod breakage which may be extremely subtle and not apparent to the patient. X-rays may reveal a progression of the curve or a break in the rods. It is important to revise and re-instrument the spinal fusion if pseudarthrosis occurs, to stabilize the deformity and prevent further progression of the scoliosis curve.

DURAL ECTASIA

Dural ectasia, a widening of the dural sac surrounding the spinal cord, can contribute to spinal pathology in NF1 (Figure 6). Dural ectasia also occurs in Marfan syndrome and associated connective tissue disorders. NF1-related dural ectasia may be observed as an independent finding or related to para-axial or intraspinal tumors. In a review of 56 patients with NF1 and dystrophic scoliosis, 38% had evidence of dural ectasia on spinal MRI, and presence of dural ectasia was a strong predictor of need for future spine surgery [Schorry et al, unpublished data]. [3].

Dural ectasia can be progressive, can result in destabilization of the spine, or can be associated with meningoceles (protrusion of the spinal meninges through a neuroforamen) or erosion of the vertebral bodies [9].

Figure 6. Dural ectasia. Dural ectasia is an expansion of the spinal canal secondary to increased hydrostatic pressure generated within the dural sleeve. It has been shown to cause severe scalloping and erosion of the vertebral bodies. Occasionally it will exit the spinal canal through the neuroforamina and cause thoracic and lumbar meningoceles.

LONG BONE DYSPLASIA

Long bone dysplasia affects between 2–5% of individuals with NF1 [12], with the most common bones affected being the tibia and fibula. Less commonly affected bones have included ulna and clavicle. Despite being a rare complication of NF1, tibial dysplasia (TD) can result in significant morbidity. Tibial dysplasia occurs in a spectrum ranging from anterolateral tibial bowing to frank pseudarthrosis with non-union of bone after fracture (Figure 7). Natural history studies have shown that tibial dysplasia in NF1 is usually evident in the first year of life; affects males more frequently than females; and is almost always unilateral (although rare bilateral cases have been reported) [13]. Typically, a patient will present with anterolateral bowing of the tibia and/or fibula in infancy. Some patients may not progress to fracture, particularly if they are braced continuously from a young age. However, up to 66% of patients with tibial dysplasia will progress to fracture and pseudarthrosis, at an average age of 4.6 years based on a natural history study [13]. Once fractured, successful surgical management is difficult, requiring multiple surgical procedures and prolonged bracing to achieve a good result. Historically, up to one-third of patients have required eventual amputation of the affected limb.

Management of Tibial Dysplasia

Bracing plays a major role in management of tibial dysplasia which has not yet fractured. Young infants with tibial dysplasia should be placed in an ankle-foot orthosis, with conversion to a knee-ankle-foot orthosis as soon as the child begins to bear weight. The brace should be worn as close as possible to 24 hours a day, with one half hour allowance for personal hygiene time, until skeletal maturity is achieved at adolescence [2]. Bracing appears to be effective in preventing fracture and pseudarthrosis in up to 1/3 of patients; however, fractures can occur due to non-compliance with bracing. Corrective osteotomy before fracture has occurred is generally not recommended, due to the risk for development of pseudarthrosis. McFarland developed a bypass fibular graft procedure (Figure 8), which has been successful in some cases in reducing risk of fracture; however, many grafts fail.

For patients who have progressed from tibial bowing to frank pseudarthrosis, various surgical techniques have been attempted. Some surgeons have chosen to use external fixation compression/distraction procedures, such as the Ilizarov frame [14]. More commonly, surgeons have used intramedullary rodding (Figure 9), with an approach including: excision of the pseudarthrosis material; placement of an intramedullary rod; and placement of autogenous bone graft from iliac crest [15, 16].

However, many patients have historically required multiple surgeries to achieve union and the re-fracture rate may be as high as 50%. Many NF1 surgeons have now begun adding recombinant human bone morphogenetic protein (rhBMP-2) to the fracture site at surgery, as an anabolic agent. Results with addition of BMP-2 have shown over 70% healing with one surgical procedure, at a mean time of 6.4 months post-operatively [17]. The addition of bisphosphonates to BMP in NF1 animal models has shown encouraging results with further improvement in bone healing [18]; however, controlled studies have not yet been conducted in human NF1 patients.

Figure 7. Congenital tibial dysplasia and pseudarthrosis. Three of the four types of congenital tibial dysplasia. a) type one with increased density in the lower mid third with no fracture; b) Fracture of the lower third with minimal displacement; c) Fracture displacement of both the tibia and fibula with pointed “sucked candy” appearance of the ends of the bones.

Figure 8. McFarland procedure. This 9 year old child presented with bilateral severe tibial bowing and NF1. She had been treated with a lateral hemiepiphyseal arrest for her ankle bowing. At a subsequent visit a stress fracture was noted at the apex of the tibial bow. She subsequently underwent bilateral medial fibular allograft by-pass procedures with subsequent incorporation of the grafts and correction of the ankle bowing.

Designing controlled clinical trials has been challenging because of the small numbers of patients treated at any one center. Clearly, better management is still needed for this rare, but highly morbid complication of NF1.

Figure 9. Intramedullary rod. This 2.5 year old female was noted at birth to have severe anterolateral bowing with subsequent fracture of tibia and fibula. She underwent a “Peter Williams” type procedure with open reduction, intramedullary rodding, bone grafting and rhBMP.

LEG LENGTH INEQUALITY/SEGMENTAL HYPERTROPHY

Leg length inequality occurs frequently in NF1; it may be related to disuse atrophy in patients with tibial dysplasia, or may occur as an isolated finding.

Segmental hypertrophy involving an entire limb and soft tissues can occur usually in association with a regional plexiform neurofibroma and may pose significant management challenges. The zones of bone and soft tissue overgrowth are usually unilateral and affect only one extremity. The osseous changes characteristically cause the bone to elongate with a wavy irregularity or thickening of the cortex. The associated plexiform neurofibromas are usually extensive involving multiple peripheral nerves and their roots in a regional plexus or the entire length of nerve. As such, resection is rarely an option.

Attempts to debulk soft tissue along with associated bone resection have not necessarily resulted in cosmetic improvement. For very large lesions, amputation and conversion to prosthetic fitting should be strongly considered. Early epiphyseal arrest of the involved bone or lengthening of the normal side has achieved a fair amount of success.

SPHENOID WING DYSPLASIA

Sphenoid wing dysplasia, one of the diagnostic criteria for NF1, usually manifests as unilateral erosive changes of the wing of the sphenoid bone of the orbit. It can be found on imaging in up to 11% of NF1 patients [12]. Most occurrences are associated with an orbital plexiform neurofibroma [19] and therefore may represent a secondary erosive effect rather than a primary osseous manifestation of NF1 [3]. Although no intervention is required in the vast majority of patients, rare cases with progressive orbital plexiform neurofibromas leading to pulsating enophthalmos have been reported [1].

PECTUS DEFORMITIES

Chest wall deformities, with varying degrees of pectus excavatum or pectus carinatum, have been reported in at least 30% of patients with NF1 when examined carefully [1]. Pectus excavatum of the lower portion of the sternum is most common, although carinatum and combined deformities can also occur.

Most mild deformities do not require surgery. Surgical repair may be chosen for cosmetic reasons or when indicated for cardiac or pulmonary decompensation. The management of pectus deformity has changed considerably from the aggressive thoracotomy procedures in the past. The Nuss procedure is a minimally invasive procedure performed by video-assisted thoracoscopy, where a metallic pre-bent plate is inserted anterior to the mediastinum and the retrodisplaced sternum is forced outward assuming its normal position [20].

GENERALIZED BONE DISORDERS

In addition to the focal, dysplastic osseous complications, more generalized bone disorders occur as well, including short stature, macrocephaly, and osteopenia. Many authors have reported stature in NF1 to be below that of age-matched peers. Studies of large populations with NF1 have shown a unimodal distribution of height shifted to the left, with 13% of patients having short stature defined as more than 2 standard deviations below the mean. Likewise, distribution of head circumference is shifted to the right, with 24% of NF1 individuals having macrocephaly [21].

OSTEOPENIA/OSTEOPOROSIS

Multiple studies have reported osteopenia or osteoporosis in up to 50% of children and adults with NF1, with mean bone mineral density (BMD) about 1 standard deviation below the mean of the general population [22, 23, 24, 25, 26]. However, the severity of osteopenia and osteoporosis in this population and its implications for bone health are still unclear. Although adults with NF1 and osteoporosis can be managed with standard anti-resorptive medications, their response to bisphosphonates may be less than that of the general population based on in vitro studies [27]. At present, there have been no studies on use of anti-resorptive medications in children with NF1. Conservative therapies, such as increased exercise and calcium and vitamin D supplementation, remain the first line of treatment for pediatric patients with NF1 and osteopenia [3].

FRACTURES

Fracture of dysplastic bone resulting in pseudarthrosis is a well-known complication of NF1 in a small subset of patients. However, despite the known reduction of BMD in individuals with NF1, limited information is available on whether this degree of bone mineral deficiency results in an increased rate of fracture of other bones, which do not appear clinically dysplastic.

Recent data have suggested a higher rate of fractures in adults with NF1. A survey study of 72 adults with NF1 in Hamburg, Germany showed the overall lifetime rate of ever having a fracture was 33%, compared to only 8% in sibling and spouse controls [28]. However, the very low fracture rate in controls raised questions of bias in the study methods. Another study involving NF1 patients of all ages reported a fracture rate of 52%, but did not have a comparison group [29].

A pediatric study of 256 children and adolescents with NF1, ages 5–20 years, found no difference in prevalence of patients with any lifetime fractures between the NF1 group without tibial dysplasia (22%) and unaffected sibling controls (25%); median number of fractures also did not differ [30]. Interestingly, there were significant differences in fracture location, with a higher frequency of fractures of the lower extremities in NF1 individuals without tibial dysplasia compared to controls. The authors concluded that children with NF1 do not appear to have a higher risk of fractures compared to non-NF1 children. It is possible that progressive osteopenia and osteoporosis do result in a higher fracture rate in older adults with NF1, but further data are needed.

BONE CYSTS; NON-OSSIFYING FIBROMAS

Benign lytic bone lesions, or non-ossifying fibromas, can be seen in the long bones in patients with NF1 (Figure 10). Riccardi and Eichner [1] noted cortical bone cysts in 10% of a series of 173 patients with NF1 who had long-bone radiographic studies performed. Non-ossifying fibromas have been reported in association with café-au-lait spots in the orthopedic literature since 1958 and called Jaffe-Campanacci syndrome; however, it is now thought that Jaffe-Campanacci syndrome is part of the variable manifestations of NF1 [31]. Non-ossifying fibromas also occur commonly in the pediatric population, and it is unclear if their incidence is increased in NF1. In the large majority of patients, these lesions are asymptomatic.

Figure 10. Multiple non-ossifying fibromas. Multiple non-ossifying fibromas in distal femur and proximal tibia in a teenager with NF1. This patient has not been restricted and followed for greater than 5 years without need for surgical intervention.

They are most frequently seen around the knee when x-rays have been obtained for sprains or strains. Most often both femurs and tibiae are involved. In a subset of patients, pathological fractures can occur [31], or microfracture may be a cause of pain.

We have generally been conservative managing these lesions, even when there are non-displaced pathological fractures. Most heal following treatment with a knee immobilizer or cast. In spite of the lucency seen radiographically, they rarely present as a displaced fracture. When seen, x-rays should be taken of both knees to confirm diagnosis.

There have been discussions questioning the benefit of percutaneous injection of bone substitutes, or treatment with bisphosphonates, but no studies have been documented. We recommend non-surgical measures for initial management of non-ossifying fibromas.

OTHERS: OSSIFYING SUBPERIOSTEAL HEMATOMA

Ossifying subperiosteal hematoma has been described as a rare osseous complication of NF1 (Figure 11). Most cases are thought to be initiated by minor fractures with subperiosteal bleeding, followed by osseous dysplasia of the hematoma [2]. The periosteum in NF1 has been described as less adherent to bone, thus predisposing it to periosteal hemorrhage. The ossifying subperiosteal hematoma occurs most frequently in the tibia and may present a clinical problem for the orthopaedic surgeon or primary care giver who does not treat this condition often.

A rapidly growing mass in a patient with minimal or no history of trauma can create concerns of infection or malignancy. The majority of cases have presented with swelling and erythema but without other signs of infection. Clinical and radiographic assessment, including MRI, will aid in differentiation of this condition from a tumor or infection.

It is important to be aware of these different findings in the physical exam and to avoid unnecessary aspiration of the lesion. The subperiosteal elevation noted in this condition is the key to differentiating between these three differential diagnoses. MRI will distinguish the subperiosteal hematoma by the rim reaction at the subperiosteal region and the fluid leveling.

Figure 11. Ossifying subperiosteal hematoma. This patient presented after minor trauma (a) with swelling, redness and pain. There is a density on the periphery of the swelling. The axial MRI (b) revealed the characteristic thick “orange rind” appearance of the periosteum but no evidence of infection. Ossification of the mass (c) and further ossification and trabeculation of the bone (d) were noted with maturity.

MUSCLE INVOLVEMENT IN NF1

Overview of musculoskeletal involvement in NF1 should include consideration of the muscle compartment as well. Motor developmental delays are well known to occur frequently in children with NF1, and have usually been attributed to CNS etiology. However, neurofibromin is strongly expressed in embryonic muscle cells [32] and its haploinsufficiency may also have a direct effect on muscle. Studies using peripheral quantitative CT scanning have shown a decrease in cross-sectional area of muscle in NF1 patients compared to controls [33]. Functional studies of muscle strength have shown children with NF1 to have a decrease in hand grip strength and lower force production in jumping when compared to controls [34; 35]. It is likely that muscle involvement in NF1 is multifactorial in etiology, with both primary and secondary effects.

CONCLUSION

A wide spectrum of osseous abnormalities can occur in individuals with NF1. Generalized abnormalities such as short stature, macrocephaly, and osteopenia, occur frequently but are usually mild. Decreased bone mineral density can lead to increased risk of fractures in adults with NF1, but does not appear to affect the pediatric population. Focal manifestations such as tibial dysplasia/pseudarthrosis and dystrophic scoliosis may be caused in part by bi-allelic inactivation of NF1 in localized tissues. Tibial dysplasia presents a challenge in management due to the risk of fracture and chronic non-union. Management with chronic bracing of non-fractured cases, and standard surgical protocols with intramedullary rodding and anabolic agents can result in improved outcome for those who have developed pseudarthrosis. Scoliosis in NF1 can be either dystrophic or non-dystrophic, presents at an early age, and affects girls and boys equally. Dystrophic curves have a high rate of progression; do not respond to bracing; and frequently require spinal fusion surgery. Current surgical recommendation for significant dystrophic curves is combined anterior and posterior spinal fusion, with immobilization post-operatively. Additional musculoskeletal features of NF1 include sphenoid wing dysplasia, dural ectasia, non-ossifying fibromas of long bones, leg length inequality, pectus deformities, ossifying subperiosteal hematomas, and decreased muscle strength. Early detection of skeletal complications and management in an orthopaedic center familiar with NF can improve outcome. Recent advances in understanding the biology of skeletal disease in NF1 raises the probability of additional biologic-based therapies for NF1 bone disease in the near future.

ABSTRACT

This chapter provides an overview of the neurocognitive, behavioral and developmental aspects of the neurofibromatosis type 1 (NF1) phenotype. Investigations into the pathogenesis of cognitive dysfunction are also presented, with a focus on human neuroimaging studies and mouse models. These studies have provided major insights into the molecular and biochemical abnormalities associated with NF1 that impact on cognitive performance. Preclinical studies suggest that pharmacological correction of these abnormalities has the potential to normalize aspects of the NF1 cognitive phenotype. These are reviewed along with the rationale for ongoing and future human clinical trials.

INTRODUCTION

Neurofibromatosis type 1 (NF1) is one of the most common single-gene disorders to affect the human nervous system, with a birth incidence of at least 1 in 2700. [1] The condition is caused by a mutation of the gene encoding neurofibromin on chromosome 17q11.2 and is characterized by a diverse range of cutaneous, neurological and neoplastic manifestations. [2, 3] Although identification of the *NF1* gene was made in 1990, diagnosis of the disorder is

usually based on the National Institutes of Health (NIH) Diagnostic Criteria, which were established in 1987 and re-evaluated without modification in 1997. [4, 5] Clinical features of NF1 include café-au-lait macules, Lisch nodules, axillary freckling, cutaneous and plexiform neurofibromas and optic gliomas. [3] Skeletal anomalies, including tibial dysplasia/pseudoarthrosis, scoliosis, and sphenoid wing dysplasia have also been well documented. [6] Although not a diagnostic feature of the condition, cognitive impairments are the greatest cause of lifetime morbidity in children with NF1, with up to 80% of children demonstrating moderate-to-severe impairments in one or more areas of cognition. [7] Cognitive deficits contribute to poor quality of life for individuals with NF1 as they result in school failure, poor peer relationships, failure to complete higher education, and limitation of career choice. The following chapter will provide an overview of cognitive, behavioral and developmental aspects of the NF1 phenotype, discuss the neural and biochemical pathologies undermining cognitive performance and will present the rationale for ongoing and future clinical trials.

1. NF1 COGNITIVE PHENOTYPE

Cognitive and behavioral impairment is one of the most common complications of NF1 in childhood and represents a major challenge to all clinicians who care for children with the condition. Children with NF1 experience noticeable difficulties in several areas of academic functioning, without consistently dramatically failing in any one particular area. [8] There is significant phenotypic variation between individuals with NF1, requiring an individualized approach to the clinical care of these children. As discussed below, cognitive and behavioral deficits manifest in a variety of ways, including academic failure due to intellectual impairment, specific learning disabilities, attention deficit-hyperactivity disorder (ADHD) as well as psychosocial maladjustment and poor social skills. The ultimate aim of all research in NF1 is to develop therapies that will improve patient quality of life. Before successful remediation of cognitive impairments and learning disabilities can occur, the NF1 phenotype needs to be carefully profiled. Over the past 20 years, significant advances have been made in describing the cognitive and behavioral phenotype of individuals with NF1 and despite the marked variability between individuals with the disorder, a number of core neuropsychological features have been identified. These in turn, provide a basis for investigations of disease mechanism and targets for therapy.

1.1. Intelligence

The earliest description of intellectual functioning in patients with NF1 was made by von Recklinghausen in 1882, when he described the first two patients with NF1. Of the first, he commented, “Apart from a great attraction to the male sex, she exhibited nothing unusual in her mental sphere”; and of the second, he reported that “His intelligence did not seem exceptional nor, on the other hand, below average.” [9] Since that time, scores of studies have reported on the intellectual capacity of individuals with NF1. Although earlier studies provided a gross overestimation of intellectual impairment due to recruitment biases, [10, 11] the

majority have reported a relative sparing of full-scale IQ, indicating that most children fall within the lower cusp of the normal range. When examining group data, the mean full-scale IQ tends to cluster around 90, rather than the normative mean of 100. [7, 12-18] Full scale IQ scores are normally distributed, indicating a true downward shift, rather than a subset of individuals skewing the group mean. [7] Indeed only around 6-8% of children with NF1 have an IQ lower than 70, compared to 2% of the general population. [7, 19] Despite the robust finding of a subtle lowering of full-scale IQ, there is no consistency between studies that have examined discrepancies between verbal and nonverbal IQ. While some report no difference between verbal and nonverbal abilities, [14, 16, 20, 21] others have reported significantly inferior verbal [22, 23] or nonverbal skills. [24-26]

It is important to take into account the limitations of intellectual measures. Although extremely valuable in providing a general level of cognitive functioning and in elucidating patterns of strengths and weaknesses, composite scales on IQ tests have often been shown to be insensitive to identifying specific cognitive impairments that are commonly described in individuals with NF1. For example, studies have highlighted minimal correlations between executive measures and IQ in children from the general population, suggesting that an IQ within the normal range does not preclude executive impairments in a given individual. [27] In order to obtain a more complete understanding of the NF1 cognitive phenotype, it is thus important to use assessment measures that evaluate narrower aspects of cognition and behavior.

1.2. Visuospatial Function

Visuospatial ability, which is the processing of visual orientation or location in space, has been one of the best described features of the NF1 cognitive phenotype and has been a significant area of focus when examining neuropsychological deficits. Eliason conducted the first study to specifically examine visuospatial abilities in 23 children with NF1. [25] Performance on the Judgment of Line Orientation task (JLO), a test requiring judgments about angulation (the orientation of various lines), was significantly abnormal in children with NF1. Since that study, the JLO has been used in a large number of studies, with the vast majority reporting impaired visuospatial judgment. [7, 16, 28-31] When examining NF1 group means, the degree of impairment has ranged from one [30] to over two [29, 32] standard deviations below the normative mean. Hyman and colleagues have also documented that 56% of children with NF1 performed at least one standard deviation below the normative mean. [7] In a more complex design, Schrimsher and colleagues examined the hypothesis that visuospatial abilities could be used to discriminate and classify children with NF1 from controls beyond parent reported ADHD symptomatology. [33] Discriminant analysis revealed that the JLO, Block Design subtest, the Recognition-Discrimination Test and the Beery Visual-Motor Integration Test were able to distinguish 92% of NF1 children from the control group. Deficits on a range of other visuospatial and visuo-perceptual measures, such as the Rey Complex Figure and the Test of Visual Perceptual Skills, have also been described. [7, 28] There is suggestion that some visuospatial measures, such as the JLO and Rey Complex Figure Test, are sensitive to executive deficits, which are also highly frequent in NF1 (see section 1.6 below). [34] The specific cluster of deficits observed across multiple visuospatial tasks, however, provides strong evidence of a true visuospatial deficit.

1.3. General Language

Language, which includes verbal expression (object naming, vocabulary and discourse), verbal comprehension, and verbal fluency, can be divided into two broad categories; expressive and receptive. Expressive language disorder is characterized by a difficulty in expressing oneself at the level expected for his/her developmental stage. Children with expressive language difficulties will often speak in short, simplified sentences, with omission of some grammatical features, such as past tense and will be able to understand language better than they are able to produce it. Receptive language disorders occur when a child has difficulties comprehending the speech of others. In most cases, a child with a receptive language difficulty will also have an expressive language disorder, which is known as a mixed receptive-expressive language disorder.

Early studies in NF1 focused much of their efforts on understanding nonverbal aspects of the disorder, giving little attention to verbal-based abilities. For example, Eliason (1986) identified a discrepancy between verbal and performance IQ (VIQ mean 99.6 vs PIQ mean 87.1) and 20 of the 23 children were impaired on tests of visuoperceptual function. [25] A follow-up study comparing children with NF1 from a learning disorders clinic to age, sex and IQ matched controls with a learning disability but without a known genetic disorder revealed that the NF1 group had significantly lower PIQ and decreased visuoperceptual performance on cognitive testing. [26] On the basis of this IQ discrepancy and the high incidence of visuoperceptual deficits, it was proposed that nonverbal learning problems were predominant in the NF1 population. Limitations of this early work, however included questionable diagnoses of NF1, high proportions of children with intracranial pathology (30%, [25] 25% [26]) that could have impacted test performance, and biased samples that were derived from learning disorders clinics and cannot be generalized to the NF1 population.

Mazzocco and colleagues were among the first researchers to undertake a detailed investigation of language in children with NF1. [30] Compared to unaffected siblings, children with NF1 ($n = 19$) performed significantly lower on tests of vocabulary, picture naming, written vocabulary, receptive language and verbal reasoning. A deficit in phonological awareness, particularly phoneme segmentation, was also identified in the NF1 group; an important finding given that phonological skills are recognized as an important precursor of literacy skills. Dilts and colleagues compared expressive and receptive language performance in 19 children with NF1 to their siblings on the Clinical Evaluation of Language Fundamentals-Revised (CELF-R) test. [28] They reported 58% of children with NF1 to have failed the screening test compared to a failure rate of 16% in the control group. Pure expressive language impairment was identified in 32% of the NF1 sample while 26% displayed combined expressive and receptive language deficits. Pure receptive language deficits were not identified in the NF1 cohort. In a study by Hyman and colleagues, broad deficits in both receptive and expressive language deficits were identified in 81 children with the condition. [7] Their greatest difficulties were in defining word meanings, comprehending simple passages, describing pictures and higher-level verbal reasoning skills. Performance on language measures was highly correlated with IQ, with only 2.5% of the sample displaying a discrepancy between FSIQ and receptive language scores and no child with NF1 demonstrated a discrepancy between FSIQ and expressive language scores. As a whole, the wide range of language skills implicated in NF1, suggest that a global language deficit is a relatively common phenotypic feature and that expressive skills are more likely to be implicated than receptive. As has been observed previously, however, it is important

to note that NF1-related language deficits nearly always occur with concurrent difficulties in other cognitive domains, such as a visuospatial impairment. [35, 36]

1.4. Learning and Memory

Memory refers to the mental process of acquiring and retaining information for later retrieval. [37] Classic models of memory conceptualize three separate stages of information processing: (1) encoding the initial processing of information and instigating a transient memory trace (2) the storage and consolidation of information contained within the memory trace into a more enduring form and (3) the retrieval of the stored information. [38] The question of whether learning and memory impairments are common in individuals with NF1 is a critical one, given the convincing evidence that hippocampal abnormalities and learning impairments can be corrected in *Nf1*^{+/-} mouse models (see Section 4.2 for detailed discussion). [39, 40] If deficits in learning and memory are identified as a phenotypic feature of children with NF1, then measures of learning and memory would be an obvious choice for a primary outcome in human trials.

Review of the literature up to 2006 by Levine and colleagues [34] indicated that while approximately half the studies investigating memory in NF1 indicated impairment in either verbal or visual memory, [29, 41] the others did not. [7, 28, 42, 43] A limitation with a number of these studies is that the measures used to assess learning and memory also rely on other complex cognitive operations, such as language or visuospatial abilities, which are well documented impairments in children with NF1. It is unclear whether such studies are reporting “true” hippocampal-based learning impairments, or whether they actually reflect a primary language or visuospatial impairment instead. Since that review, several studies have published data on visuospatial learning and memory in NF1, with the purpose of drawing a phenotypic parallel between NF1 murine models and humans with the condition. [44, 45] Ullrich and colleagues examined visuospatial learning in children with NF1 (n = 10) and sibling controls (n = 6) using a computerized Arena Maze task. [44] This virtual environment task, which assesses learning of spatial navigation using relations between distal cues, was developed as a human analogue of the Morris Water Maze; the visuospatial learning task often employed in mice studies. [39, 40] Children were required to navigate to a target hidden in the arena over multiple learning trials. Although children with NF1 demonstrated improvements in navigation over repeated trials, they displayed greater difficulty in earlier search trials compared with unaffected siblings. Performance of the NF1 group on the final trial (a probe trial in which the target was removed) indicated less dwell time in the target quadrant, suggesting recall of the target location was inferior to control participants. In another study, Payne and colleagues used a visuospatial Paired Associate Learning (PAL) test from the Cambridge Neuropsychological Test Automated Battery (CANTAB); a collection neuropsychological tests specifically designed to improve the comparative assessment of cognition from animals to humans. [46] Participants were required to make arbitrary associations between a simple visual pattern and a spatial location. While the task commenced with only one paired association to be recalled, it became progressively more difficult with eight paired associations required to be formed in the final stage. The PAL task has been well validated in human clinical populations with damage to mesial temporal lobe structures [47-49] and in monkey studies which report impaired learning following administration of NMDA antagonists which block long term potentiation

(LTP) in the hippocampus. [50, 51] The authors reported that compared to controls ($n = 29$), children with NF1 ($n = 71$) displayed a reduced capacity to form arbitrary visuospatial associations after an initial presentation of the stimuli and a poorer learning curve across repeated presentations of the same stimuli. Interrelationships between performance on the PAL task and other cognitive abilities that may potentially influence performance on the task, such as intelligence, attention and visuospatial function were also explored. While regression analysis indicated that FSIQ was a significant predictor of visuospatial learning, the NF1 group was found to make errors at twice the rate of the control group after controlling for the influence of FSIQ, providing convincing evidence for a hippocampal-based learning impairment in children with NF1.

1.5. Attention

Attention is the cognitive process of selectively filtering out irrelevant aspects of environmental stimuli in order to benefit processing of behaviorally relevant information. In everyday life, attention is mediated by two partially segregated networks – a cognitive (top-down) network that is under an individual's control, guided by knowledge, expectation and current goals, and a bottom-up network that automatically orients attention to sensory stimuli that are unexpected, abrupt, novel, salient or potentially dangerous. [52] The dynamic interaction between these top-down and bottom-up processes control where and how we allocate attentional resources. This distinction is critical, as evidence suggests that different neurocognitive processes control these two attentional mechanisms [52] and that distractibility and inattentiveness might arise from an increase in bottom-up interference or from a failure to engage top-down control mechanisms. [53]

Attention difficulties are one of the most commonly described impairments within the NF1 literature. The Test of Everyday Attention for Children (TEA-Ch) has been used in a number of studies to assess different attentional demands placed on children. In a large sample of children with NF1 ($n = 199$), Payne and colleagues demonstrated that children with NF1 performed significantly poorer than sibling controls ($n = 55$) and normative data on measures of divided attention (61% of the NF1 group fell more than 1 SD below normative data), sustained attention (56%), attentional control (54%) and selective attention (39%). [21] Other studies using the TEA-Ch have also indicated impairments in divided attention, [15, 54] sustained attention, [7, 15, 54] and attentional control. [7, 15] Continuous performance tests (CPTs), such as Conners CPT-II and the Test of Variables of Attention (TOVA), have also been used to assess sustained attention and vigilance. Increased omission errors, which are recorded when participants fail to respond to a target, have been documented in children with NF1 when compared to unaffected siblings [13, 30] and normative data. [41, 54] Although this finding is not universal, [28, 55] the use of CPTs to identify sustained attention impairments is not necessarily straightforward. By their nature, CPTs tend to be drawn out and monotonous, possibly resulting in children changing the strictness of their response criterion. As such, poor performance on these tasks may be due to children becoming less strict in deciding whether a signal is a target or not, and not because their ability to attend to the target is impaired. Furthermore, like other cognitive measures, they are administered in controlled conditions that lack the environmental challenges faced by the child in the real world.

In an attempt to overcome these limitations, Gilboa and colleagues assessed attention function in children with NF1 using a more ecologically valid, virtual reality system. [56] Their Virtual Classroom consisted of a head-mounted display that simulates a real-world classroom. Children were required to monitor digit sequences presented on a “blackboard” over a 10 minute period while real-world classroom distractions, such as ambient classroom noises, a person walking into the room and a flying paper aeroplane, were occurring. Results showed that the NF1 group ($n = 29$) made more omission errors than controls ($n = 25$), indicating a reduced focus on the target stimuli. There was also a significant relationship between omission errors and a parent rating scale of inattention, supporting the validity of the Virtual Classroom task and the hypothesis that NF1 is characterized by inattention. It would be interesting for future research to examine the associations between outcomes of the Virtual Classroom task and traditional cognitive measures of attention.

1.6. Executive Functions

Executive functions are interrelated cognitive and behavioral skills that are responsible for purposeful, goal-oriented activity, such as planning/organization, cognitive flexibility, and impulse control. [57] A primary purpose of the executive functioning system is to facilitate our adaption to novel situations, particularly when routine actions are insufficient. [58] From a neuropsychological perspective, executive functioning plays a unique “command” role in terms of guiding and regulating thought and behavior and is considered an umbrella term for cognitive processes such as planning/organization, mental flexibility, initiation and monitoring of actions, problem solving, working memory and the ability to inhibit impulses. Neuroimaging and brain lesion studies converge on the view that executive functions are critically dependent on the frontal cortex; indeed the terms ‘executive function’ and ‘frontal lobe’ are often used synonymously. However, recent theories have suggested that this view is overly simplistic and subcortical regions such as the basal ganglia, cingulate gyrus, cerebellum and thalamus are also critically involved. The link between this neural circuitry and executive functioning is demonstrated by a range of neurological and psychiatric disorders with prominent involvement of prefrontal and frontostriatal circuitry, such as attention deficit hyperactivity disorder, [59] autism spectrum disorders [60] and schizophrenia; [61] all of which are characterized by impairments of the executive system.

Early documentation of executive impairments in NF1 largely consisted of anecdotal reports and behavioral descriptions, including increased impulsivity, distractibility, failure to plan, an unstructured learning style and monochromatic problem solving strategies (such that one strategy is excessively used at the expense of more efficient and effective strategies). [20, 25, 62] Initial studies using cognitive-based measures reported that attention, sequencing and verbal working memory, as assessed with the Freedom from Distractibility Index from the Wechsler intelligence scales, were impaired in children with NF1. [25, 63] Since these early studies, a number of empirical studies have explicitly examined executive abilities in children with NF1, confirming executive dysfunction as a core phenotypic feature of the condition. Deficits in cognitive control, [7, 15, 21, 41, 64, 65] inhibitory control, [16, 65, 66] working memory, [7, 15, 16, 66, 67] abstract concept formation, [29] and spatial/action planning [7, 15, 17] have been identified. A number of studies reporting on executive functioning in NF1 have controlled for other cognitive abilities, such as intelligence or visuospatial skills, which on the

whole, indicate that executive impairments persist over and above any lowering of intelligence. Ferner and colleagues reported group differences between individuals with NF1 and normal controls on measures of selective and divided attention after including IQ as a covariate. [41] Impairments on measures of spatial working memory and inhibitory control have also been reported after controlling for verbal intellectual and visuospatial skills. [16] Similarly, significantly reduced planning abilities have also been reported to remain after controlling for IQ [7, 17] and visuospatial abilities. [17]

Perhaps more so than any other area of cognition, the valid identification of impairments of executive function is difficult and often elusive. Indeed, it is generally accepted that traditional standardized neurocognitive measures of executive function may lack sufficient sensitivity to relate directly to the multidimensional nature of situations experienced in daily life, particularly in pediatric populations. [68, 69] That is, they have questionable ecological validity; the degree to which test performance corresponds to real world performance. [70] For example, these measures (a) are administered in a structured clinic setting (b) are dependent of lower-level cognitive skills, such as language, visuospatial skills and memory, which are commonly impaired in children with NF1 (c) have often been designed for use in adult populations (usually to determine the presence/absence of a lesion) and subsequently adapted for children, and (d) are often dissociated with real-world behavior. In a large sample ($n = 199$), Payne and colleagues assessed the frequency of everyday attention and executive impairments in children with NF1 and examined the relationship between these functional impairments and performance on neurocognitive measures. In addition to everyday impairments in attention, children with NF1 were reported to display significantly more executive deficits in their daily activities than controls. Working memory (60% impaired), self-monitoring (59%) and planning and organization (58%) were the most common executive abilities at risk of impairment. Somewhat surprisingly, there were no associations between many neurocognitive measures of executive function (such as the Tower of London, Children's Category Test and Controlled Oral Word Association Test) and the everyday skills they purport to assess. The best neurocognitive predictors of functional executive abilities were measures of attentional control and working/immediate memory. These findings highlight the importance of supplementing neuropsychological assessments with functional assessment tools to provide a more accurate and sensitive encapsulation of a child's strengths and weaknesses to guide remediation programs.

1.7. Academic Achievement and Learning Disability

The neurocognitive impairments experienced by children with NF1 place the majority of them at significant risk of academic underachievement. [12, 19, 71] North and colleagues reported 65% of their sample of children with NF1 ($n = 40$) had impairment in at least one area of academic achievement; 45% performed more than two years below chronological age on tests of reading accuracy; 48% displayed impaired performance on measures of reading comprehension; and 28% were reported to fall more than 1.96 standard deviations below the mean on a standardized mathematics test. [20] More recently, Krab and colleagues calculated a 'learning efficacy' score, based on a discrepancy between academic age-equivalent scores and a child's chronological age. [12] They reported that 75% of children with NF1 performed more than one standard deviation below grade peers in at least one of the domains of reading,

spelling or mathematics. Only 10% of children did not demonstrate any school-functioning problems in this cohort and those without apparent learning disabilities still frequently displayed neurocognitive deficits. A current issue in the NF1 literature is whether a learning disability should be identified in children who are performing significantly worse than a comparison group or normative data, or whether a significant discrepancy between academic achievement scores and the individual's IQ is additionally required. [8] Hyman and colleagues examined this distinction by examining frequencies of specific learning disability (SLD; academic difficulties in the presence of normal IQ) and general learning disability (GLD; academic difficulties in the presence of low IQ) in children with NF1. [19] Using the Wechsler Individual Achievement Test, the authors identified SLD in 20% of their NF1 sample, GLD in 32% and normal academic achievement in 48%. Interestingly, 15 of the 16 children identified as having a SLD were male, suggesting that females with NF1 may not be at any greater risk of SLD than those in the general population. [19] This gender effect will ideally be confirmed in future studies.

Research examining the reading performance of children with NF1 has typically employed academic achievement measures to identify reading disabilities based on significant discrepancies between intellectual functioning and reading achievement. [30, 72] For example, Cutting and colleagues found children with NF1 had single word reading and reading comprehension deficits when compared with normal controls. [72] Other skills associated with reading, including rapid naming and phoneme segmentation, were also delayed. Similarly, Mazzocco and colleagues reported a higher incidence of reading deficits among school-aged children with NF1, based on Cluster Scores on the Woodcock-Johnson-Revised, when compared to unaffected siblings. [30] Children with NF1 were found to have verbal weaknesses, including deficits in verbal reasoning, vocabulary, picture naming and receptive language. More basic linguistic deficits were also identified on measures of phonological memory and phoneme segmentation. A recent study compared the reading profile of children with NF1 to those with idiopathic reading disability. [73] Results indicated that children with NF1 and reading disability performed similarly to children with idiopathic reading disability on measures of phonological awareness, rapid naming and reading comprehension. However, the NF1 + reading disability group displayed pronounced visuospatial deficits when compared to children with idiopathic reading disability and typically developing readers. While visuospatial deficits are considered a hallmark feature of NF1, it is interesting to note that children with NF1 without reading disability did not have a distinct visuospatial weakness. In addition, visuospatial skills only correlated with basic reading ability in the NF1 + reading disability group. In a further study, Watt and colleagues reported that despite normal levels of intellectual functioning, 67% of children with NF1 ($n = 30$) demonstrated impaired non-word reading. [74] Non-words are pronounceable nonsense words that require the utilization of common rule-based grapheme-to-phoneme correspondences to correctly sound out the word (e.g., "peef"). These findings demonstrate that a significant proportion of children with NF1 experience difficulty employing spelling-to-sound rules to assemble a pronunciation when reading.

In addition to examining literacy skills and linguistic ability of children with NF1, a number of studies have also explored mathematic ability. As is pointed out by Moore, the performance of children with NF1 on mathematics tasks covers a broad range of abilities, but the distribution of scores is shifted somewhat lower than the population mean. [75] Most studies examining math ability have reported deficits on measures of math calculations [15, 19, 72, 76] and math

word problems. [15, 30, 77] Although the mechanisms underlying mathematical learning disability in children with NF1 are not clear, evidence from the idiopathic mathematical learning disability literature suggests that cognitive impairments in working memory, visuospatial skills and ADHD can all affect math ability. [75] Recent research in a large NF1 cohort has started to elucidate some of the cognitive mechanisms underlying math ability using backward linear regression models. [15] Attentional control (Creature Counting Subtest from the TEA-Ch) was the best predictor of math ability in children with a comorbid diagnosis of NF1 and ADHD and attentional control and visuospatial skills (JLO) were the best predictors of math achievement in children with NF1 only. Given that the Creature Counting subtest places demands on inhibition, working memory and set shifting, these findings suggest that poor performance on math tasks can be partially attributed to executive sub-skills that direct other higher-order processes.

2. THE SOCIAL AND BEHAVIORAL PHENOTYPE

In addition to cognitive impairments, NF1 patients also demonstrate a number of social and behavioral deficits. One of the most prevalent behavioral phenotypes is ADHD. Characterized by persistent and pervasive symptoms of inattention and/or hyperactivity/impulsivity, comorbid ADHD has been reported to occur with frequencies varying from 17% [78] to 50% of pediatric NF1 samples. [29] The extent of this range is most likely due to variations in clinic demographics, sampling biases and inconsistencies in diagnostic methodology. Prevalence rates in larger samples of children ($n = 80$ -199) assessed on a consecutive basis from Neurofibromatosis Clinics go some way to diminishing some of these biases and estimate the frequency at approximately 30-40%; [7, 15, 16] a marked increase compared to estimates in the general population (3-5% of school aged children). [79]

A burgeoning area of interest in the NF1 literature is the relationship and impact of ADHD on the cognitive phenotype of individuals with the condition, with studies for the most part, examining phenotypic differences of children with NF1 to those who also meet ADHD criteria. [15-17, 64, 80] Results to date lack consistency. For example, while Lidzba and colleagues [80] reported that symptoms of ADHD (with or without hyperactivity) have a negative impact on intellectual performance of individuals with NF1, other retrospective and prospective studies report that ADHD has no impact on the intellectual abilities of children with NF1. [15-17] In a large retrospective study ($n = 192$), Pride and colleagues reported that while children with NF1 and comorbid ADHD exhibited poorer academic achievement, and sustained attention abilities than children with NF1 only; other aspects of attention, visuospatial skills, memory and intellectual function were no more impaired in children with NF1 and ADHD than those without the additional comorbidity. [15] With respect to executive functions, a recent prospective study examined whether spatial working memory and response inhibition – executive abilities commonly impaired in ADHD cohorts [81] – were impaired in children with NF1 only ($n = 49$), and whether a comorbid diagnosis of ADHD ($n = 35$) exacerbated any executive deficits. [16] Results revealed that children with NF1, with or without comorbid ADHD, displayed spatial working memory and inhibitory control impairments. Interestingly, there was no difference in the degree of impairment between the NF1 only and NF1+ADHD groups, suggesting that ADHD comorbidity did not exacerbate the degree of executive

dysfunction. Similarly, in a study investigating cognitive and motor control in NF1, Huijbregts and colleagues reported cognitive control deficits in their NF1 cohort ($n = 30$), seven of whom were diagnosed with ADHD. After excluding participants with ADHD, cognitive control deficits in the NF1 only participants remained. [64] In another study, children with NF1 and ADHD have been reported to display poorer spatial planning than an NF1-only group on one measure (Tower test), but not on others (Mazes, Rey Complex Figure Test). [17] Taken together, these studies suggest that executive impairments are not uniquely associated with ADHD in NF1; it is clear that other cognitive and/or psychological factors underlie the ADHD phenotype. Furthermore, a diagnosis of ADHD does not explain the cognitive problems in NF1 – the cognitive, behavioral and motor impairments observed in individuals with NF1 are consequences of NF1-related pathology rather than an independent ADHD condition. This distinction has important implications for future clinical trials investigating pharmacological and cognitive-based interventions in NF1, such that trials should not only include children that satisfy ADHD diagnostic criteria, but also those with cognitive and/or functional impairments without an ADHD phenotype.

A currently unresolved issue in the literature is whether ADHD in children with NF1 is a cognitive-behavioral phenotype of the disorder or whether it is a comorbid condition in a subsample of children. There is evidence for quite distinct phenotypic differences between children with NF1 and comorbid ADHD and those with ADHD from the general population. The majority of studies report that children with NF1 are more likely to meet the criteria of the inattentive or combined subtype of ADHD rather than the hyperactive/impulsive type, which is the most common subtype in children with ADHD alone. [15] In the general population, the frequency of ADHD is up to nine times higher in males than females, whereas both genders are equally affected in NF1. [82] As is discussed by Huijbregts, structural brain abnormalities observed in individuals with NF1 and ADHD also appear to differ quite markedly from observations in those with ADHD from the general population. [64, 83] While ADHD is associated with smaller volumes in a number of anatomic regions, such as the right prefrontal cortex, corpus callosum, caudate and cerebellum, [84] NF1 is often associated with macrocephaly, increased grey matter volume, abnormal grey-to-white matter ratios and an enlarged corpus callosum (see Section 5.1.1. below). [42, 64, 85] These differences add weight to the argument that ADHD diagnoses in NF1 are based on a more severe behavioral phenotype (NF1-related pathology) rather than an independent comorbid condition such as ADHD. In order to further understand the behavioral mechanisms underlying the ADHD phenotype in NF1, it is important for future studies to include ADHD control groups from the general population to compare cognitive, psychological and neuroanatomic constructs to help our understanding of the degree of cognitive and biological convergence between these two disorders.

Social dysfunction is also a prominent feature of NF1. Parents of children with NF1 commonly describe their child as shy or awkward with peers and indicate they are often the victims of teasing and bullying. As a result, increasing effort over the last decade has been devoted to the analysis of social skills in NF1. Responses on parent and teacher behavioral questionnaires have indicated poorer social skills, social outcomes and increased social problems in children with NF1 compared to unaffected children. [28, 86-88] Adults with NF1 also demonstrate a lower frequency of pro-social behaviours (such as eye-contact when speaking, smiling when they see someone) than unaffected matched controls, suggesting that social dysfunction continues into adulthood. [89]

There is currently no established theory to explain social dysfunction in NF1 and investigations into the processes that may influence the link between NF1, central nervous system (CNS) functioning and social behaviour have rarely occurred. The evidence for cognitive dysfunction underlying social and behavioral problems in NF1 is mixed. While some have reported no relationship between cognitive measures and social behaviour, [65] others have reported a significant difference between social processing abilities of children with NF1 and a healthy control group that disappeared once cognitive processing abilities were accounted for. [67] Others studies have found a link between social problems and greater disease severity in terms of neurological involvement (CNS involvement, cognition, and attention deficit hyperactivity disorder). [86, 88, 90]

One area that has received insufficient attention is social cognitive abilities in NF1. This is particularly relevant given that an increased incidence of autistic traits have been reported in children with NF1. [90] Social cognition encompasses a broad set of processes that allow a person to recognize, understand and behave appropriately with respect to socially relevant stimuli; processes that are critical for adequate social functioning. [91] Huijbregts and colleagues examined social information processing in 32 children with NF1 and 32 controls and found that children with NF1 displayed a weakness with facial recognition and processing fear and anger. [67] A more recent study using voxel-based morphometry examined the relationship between grey matter (GM) brain volume and social perception in 16 adults with NF1 and compared region of interest volumes to 16 matched controls. [92] Although the sample size was limited, results indicated that adults with NF1 experience difficulty processing anger and interpreting social exchanges involving subtle sarcasm. Structural abnormalities in a number of brain regions associated with social cognition were also documented, including the posterior cingulum, ventromedial prefrontal cortex and the superior temporal cortex; the latter correlating with social perception performance. These two studies raise important questions regarding the underlying causes of social dysfunction in NF1 and open several avenues for further investigation. Future work should focus on the relationship between social functioning, social cognitive processes and cognitive dysfunction to help delineate the underlying causes for social dysfunction in NF1.

3. NEURODEVELOPMENTAL ASPECTS

Parents of children with NF1 often raise concern about their child's development around their second or third birthday. Despite this, the majority of studies have limited their investigations to children of school age (6 to 16 years of age). Very few studies have addressed issues of cognitive development in young toddlers and infants; a developmental period which is crucial, as interventions are more likely to have positive outcomes when commenced during this period of increased neural and behavioral plasticity. Early studies that have examined the cognitive profile of young children with NF1 revealed delays in cognition, motor skills and language. [24, 62] Interpretation of these results, however, is limited by either a small sample size [24] or the lack of an appropriate control cohort. [62] A more recent study examining cognition in 39 toddlers with NF1 (aged 21-30 months) and 42 age-matched controls reported that NF1 participants displayed significantly poorer mental and motor development than controls. [93] Parental responses also indicated that most of the children with NF1 experienced

language delays; however group differences in behavior and executive functioning were not evident during this developmental period. Language delays have also been reported in a study which used the preschool version of the CELF to assess receptive and expressive language development in 19 young children with NF1. [94] Results revealed that 37% of the sample demonstrated delays in expressive language and 37% demonstrated delays in receptive language. The characteristic downward shift in IQ, poor visuospatial skills and inattention have also been identified in another cohort of preschool-aged children. [13] Taken together, these findings indicate that cognitive and language delays manifest early in life, can be measured before the child starts school, and appear to mirror the difficulties identified in older children. As such, early assessment and intervention should be considered as it may help circumvent the negative impact of cognitive and motor dysfunction associated with NF1.

Only a handful of studies have explored the cognitive correlates of NF1 in adults. [14, 95-97] Ferner and colleagues examined cognitive function in a large sample of adults and children with NF1. [14] The NF1 group displayed lower IQ scores, reading ability, verbal memory and attention than controls. Difficulties in developing strategies for complex, novel tasks were also reported. Zöller and colleagues examined cognitive performance in 30 adults with NF1. [95] Compared to controls, the NF1 group exhibited deficits in inductive reasoning, visuoconstructive ability, visual and tactual memory, logic abstraction, coordination and mental flexibility. Depressive symptoms were also associated with reduced psychomotor speed. Pavol and colleagues examined the hypothesis that performance on measures of visuospatial and attention abilities could be used to differentiate adults with NF1 ($n = 20$) and unaffected controls. [97] Two tests of visuospatial ability and a language measure were found to be the best predictors of group membership, with a measure of visuomotor integration the best discriminator between groups. Reading difficulties have also been reported to occur in adults with NF1, with 13% of patients experiencing difficulties reading a passage aloud and an additional 63% demonstrating paraphrase misreadings (e.g., reading “the one who could” as “the one of them who could”). [96] Difficulties with descriptive writing (40%) and spelling (50%) were also prominent.

Little is known about the natural history of cognitive functioning from childhood to adulthood in patients with NF1. Two hypotheses appear to emerge from the limited literature that exists. First, some cross-sectional studies suggest improvements in general cognitive functioning from childhood to adulthood [98] as well as specific improvements in language and motor skills. [95] The second hypothesis, which asserts a static cognitive profile, is based on evidence from cross-sectional studies that report a stable IQ throughout childhood and adolescence [99] and between childhood and adulthood. [14]

Longitudinal studies are beginning to provide insight into the natural history of cognitive impairment in NF1. Cutting and colleagues conducted growth curve analyses on six cognitive measures over repeated time points in 19 children and adolescents with NF1. [100] Performance of the NF1 group did not improve relative to sibling controls on impaired measures (JLO, Vocabulary and Block Design), indicating stable function over time. Hyman and colleagues prospectively followed 32 patients with NF1 and 11 unaffected sibling controls, examining cognition during childhood (mean age 12.6 years) and again 8 years later (mean age 20.1 years). [43] Although cognitive performance was reported to be stable across this eight year period, reassessment of a subset ($n = 18$) of this cohort 10 years later indicated a significant improvement in intellectual function. [101] As discussed below (see Section 4.1.1), cognitive improvement was limited to individuals with NF1-specific brain lesions in childhood. A large

prospective longitudinal study, spanning childhood to adulthood, utilizing structural neuroimaging and a comprehensive cognitive battery at each time-point, is needed to confirm and extend these findings.

4. PATHOGENESIS OF COGNITIVE IMPAIRMENTS

Both human data and animal models are beginning to provide crucial insights into the underlying pathological correlates of cognitive dysfunction in NF1. It is critical to understand these mechanisms before directed clinical trials can be implemented. There is already compelling evidence for a relationship between cognitive dysfunction and a number of structural and functional brain abnormalities. [102] As discussed below (see Section 4.2), mouse models have also proven essential in revealing the molecular and biochemical abnormalities that occur due to a loss of neurofibromin and the impact of these abnormalities on cognition.

4.1. Human Neuroimaging Studies

4.1.1. Structural

Macrocephaly and increased brain size have been reported in up to 50% of children with NF1. [103-105] Several studies suggest that increased brain volume in children with NF1 appears to be largely driven by an increase in white matter; predominately in frontal regions and the corpus callosum. There is, however, also indication of increased grey matter volume in posterior regions. [105] Although the majority of studies have repeatedly demonstrated a lack of any association between macrocephaly and neurocognitive performance, [7, 71, 106, 107] some have reported a number of associations between grey matter properties and cognition. Moore and colleagues reported a larger discrepancy between intelligence and academic achievement in children with increased grey matter volume. [42] In contrast, Said and colleagues found a relationship between decreased grey matter volumes and reduced visuospatial functioning. [108] Others have reported absence of the normal positive relationship between grey matter volume and intelligence. [109] The diverse nature of these associations, however, makes it difficult to make firm conclusions regarding the role of grey matter anomalies on cognitive performance.

A number of studies have reported on the influence of focal neuroanatomical abnormalities on cognition. Billingsley and colleagues reported a loss of the normal asymmetry of the planum temporale in children with NF1; a structure within the sylvian fissure located on the on the superior surface of the temporal lobe. [110] Greater symmetry between left and right hemispheres was associated with reduced reading ability and math performance in relation to IQ scores, suggesting that abnormal development of the planum temporale could be a risk factor for specific learning deficits in children with NF1. A relationship between language and an atypical right inferior frontal gyrus has also been documented, with atypical morphology associated with increased language and academic performance. [76] An enlarged corpus callosum, the primary white matter tract connecting the left and right hemispheres, has also been reported in a number of studies, [42, 85, 111, 112] some of which controlled for total brain

size. [85, 112] Correlations between corpus callosum cross sectional area and cognition have also been documented. A larger corpus callosum has been associated with academic underachievement, lower intelligence, executive functioning, and visual spatial impairment, [85, 113] while a smaller corpus callosum has been associated with reduced attention abilities. [111]

NF1 is also associated with focal areas of high intensity observed on T2-weighted MRI (T2H) which are seen in 60-80% of children with the disorder. [114-116] T2H commonly occur in the basal ganglia, cerebellum, brainstem, thalamus and subcortical white matter and are thought to represent areas of increased fluid content within the myelin sheath or dysplastic areas of white matter formation. [115] While the number, size and intensity of T2H have been reported to decrease with age, this is limited to those occurring within the basal ganglia, thalamus and brainstem. Lesions located within the cerebral hemispheres, hippocampus and deep white matter appear to remain stable over time, possibly indicating a different pathological basis. [43, 101, 115] The question of whether T2H represent biological markers for cognitive dysfunction is controversial. While some moderate-to-large studies using clinic-based samples and quantitative neuropsychological measures have identified a significant association between the presence of T2H and a lowering of IQ, [117, 118] others have not. [18, 78] Although evidence for an association between cognitive impairment and either the presence or number of T2H remains contentious, studies drawing parallels between cognition and T2H location have consistently identified a relationship between thalamic lesions and generalized cognitive impairment, including borderline IQ. [114, 116, 119, 120] Preliminary evidence from a recent longitudinal study following a cohort of individuals with NF1 (n = 18) over an 18 year period provides evidence of a relationship between T2H status in childhood and cognitive changes in later life. [101] The authors reported a significant increase in general cognitive function in patients with discrete T2H in childhood; patients without lesions in childhood exhibited a stable profile over the duration of the study. These results raise the possibility that resolution of T2H over time is accompanied by an improvement in general cognitive performance. This needs to be confirmed, however, in a larger prospective study that includes longitudinal examination of the relationship between T2H location (particularly in the thalamus) and cognitive performance.

4.1.2. Functional

When a brain region is performing a task, it consumes more oxygen. To meet this increased demand, blood flow is increased to the active area. Functional MRI (fMRI) detects these changes in blood oxygenation and flow that occur in response to neural activity via the blood oxygen level-dependent (BOLD) response. [121] By comparing activation maps of children with NF1 to comparison groups, it is possible to identify abnormal neural systems and how they relate to cognitive performance. Despite fMRI providing non-invasive neural activation maps with excellent spatial and good temporal resolution, there has been surprisingly little published within the NF1 literature. An area that has received some attention in the NF1 literature is the neural correlates of visuospatial impairment. [31, 77] In one study, 13 children with NF1 and 13 unaffected controls performed an analogue of the JLO task in the scanner. [31] Comparison of activation patterns revealed that the NF1 group demonstrated significantly greater left hemisphere activation as opposed to the dominant right hemisphere activation in controls. These results suggest a functional correlate of visuospatial impairment in NF1 may be a dysfunctional right hemisphere network. Billingsley and colleagues have also reported

greater activity in posterior relative to anterior cortical regions in children with NF1 during a letter/number rotation task. [77] The authors hypothesized that this finding may reflect an alternative resource allocation due to functional inefficiencies in anterior regions.

Functional MRI has also been used to investigate the neural bases for phonologic processing in NF1. [122] Compared to controls, children with NF1 demonstrated less inferior frontal activation relative to temporoparietal activation on a written rhyming decision task. Behavioral performance on the fMRI tasks was related to a number of academic literacy measures for the NF1 group, including letter-word identification and a spelling task. The authors speculated that this pattern could reflect recruitment of more posterior than frontal regions as a result of functional inefficiency of the frontal lobe. A further study, investigating the functional correlates of spatial working memory, has also implicated frontal lobe inefficiencies in young adults with NF1. [123] Compared to controls, the NF1 group displayed less task-related activation in the dorsal lateral prefrontal cortex, parietal cortex, and striatum while completing a spatial working memory task. The degree of dorsolateral PFC activation correlated with behavioral performance on the task.

As clinical trials continue in NF1 cohorts (See Section 5.0), neuroimaging techniques will begin to provide valuable surrogate outcomes by comparing neural activity pre- versus post-treatment. A number of neuroimaging techniques could be used in such a role, the most obvious being task-based fMRI, in which neural activation is measured while the patient performs a cognitive task in the scanner. Resting state fMRI (R-fMRI) is a very promising and powerful neuroimaging tool that could also prove a valuable biomarker. It examines regional connectivity by recording and analysing spontaneous modulations in the BOLD response in the absence of any explicit input or output. Resting state fMRI has been shown to predict the task-response properties of brain regions [124, 125] identify participants' aptitude for different cognitive tasks, [126, 127] and is well suited to monitoring treatment effects by studying participants before and after treatment. Recently published data from a Phase I treatment trial of lovastatin in a subset of seven patients with NF1 suggest that treatment increased functional connectivity within the medial prefrontal lobe and posterior cingulate cortex, highlighting the sensitivity of the technology. [128]

Taken together, the neuroimaging literature to date highlights both structural and functional brain abnormalities in individuals with NF1; abnormalities that contribute to the cognitive impairments commonly observed in the condition. Due to the relatively small number of studies, variable methodologies, different ascertainment procedures, often small sample sizes and heterogeneous nature of the disorder, clear consistent findings are still emerging. As has been noted elsewhere, it is important that future studies investigate specific hypotheses in well-defined subsamples using multiple control groups where appropriate. [102] Assimilating knowledge of the molecular mechanisms underlying cognitive and behavioral impairments in NF1 (see Section 4.2 below) and data on the functional pathways in NF1 and ADHD will significantly further knowledge in these areas and guide the design of future clinical and preclinical trials.

4.2. Insights from Animal Models

Mouse models have been critical experimental tools in which to explore the etiology of cognitive deficits in NF1. The NF1 gene encodes neurofibromin, a 250kDa protein that plays

important roles in several biochemical processes, including modulation of cAMP levels, [129] microtubule binding, [130] and mTOR signaling. [131, 132] It is the effect of neurofibromin on RAS, a protein implicated in cell proliferation and differentiation that has been most extensively investigated. [133-135]

Mice with a heterozygous null mutation of the *Nf1* gene have been the predominant model used to study the result of aberrant RAS signaling on cognition and the cognitive and behavioral consequences of mutations at *Nf1* have been characterized in these mice across a series of detailed studies. [39, 40, 136, 137] Spatial learning deficits in the hidden version of the Morris water maze have been replicated multiple times, with *Nf1*^{+/-} mice requiring more training trials than wild-type littermates to locate the position of the hidden platform; a performance suggestive of impaired hippocampal-based learning. While *Nf1*^{+/-} mice also show deficits in contextual conditioning, other forms of learning, such as classical conditioning and simple associative learning remain intact. [137] In addition to hippocampal-based learning deficits, *Nf1*^{+/-} mice have also been reported to experience attention impairments in a lateralized reaction time task (a measure designed to assess attention processes) and significantly reduced prepulse inhibition; a measure of sensory gating whereby a startle reflex is inhibited if preceded by a weak prestimulus. [40]

Hyperactivation of the RAS-MAPK signaling cascade has been proposed as the core mechanism underlying cognitive impairment in *Nf1*^{+/-} mice. An increase in RAS signaling causes an increase in activity-dependent GABA release, resulting in an imbalance between inhibitory and excitatory processes. [138] In the hippocampus, this has been shown to significantly reduce long term potentiation (LTP), a form of synaptic plasticity resulting in an increased strength of synaptic transmission that is required for effective learning and memory. It is a deficit in LTP that is thought to underlie the learning and memory impairments in *Nf1*^{+/-} mice. [40, 137, 139] This assertion has been reinforced by preclinical studies that have manipulated levels of active RAS and GABA inhibition. Costa and colleagues bred *Nf1*^{+/-} mice and mice deficient in active RAS (K-RAS^{+/-} mice) and tested both groups on a hidden water maze task. [136] Genetic manipulation to reduce RAS resulted in equivalent performance between the wild-type mice and *Nf1*^{+/-}/K-RAS^{+/-} mice, suggesting learning impairments in *Nf1*^{+/-} mice may be caused by excessive RAS activity. Pharmacological manipulation has also been used to decrease RAS hyperactivation. *Nf1*^{+/-} mice were given lovastatin; an agent commonly used to treat hyperlipidemia in children and adults which also decreases p21RAS isoprenylation. [40] After several days of treatment, *Nf1*^{+/-} mice medicated with lovastatin demonstrated improved performance relative to the placebo group on tasks of hippocampal-based learning (hidden version of the Morris water maze) and attention (lateralized reaction time task). Importantly, lovastatin also reversed deficits in LTP and normalized elevated p21RAS/MAPK activity, providing a physiological basis for the cognitive improvement. Learning deficits associated with a mutation at *Nf1* have also been rescued by a subthreshold dose of GABA_A antagonist. [137]

While cognitive impairments caused by dysregulation of the RAS-MAPK pathway have been demonstrated as one potentially reversible aspect of the NF1 cognitive phenotype, a series of recent experiments have identified the dopaminergic pathway as an alternative target for cognitive treatment by demonstrating that reduced dopamine (DA) in the striatum may underlie attention system dysfunction in *Nf1* mice (*Nf1*^{+/-} strain with GFAP⁺ cell bi-allelic *Nf1* gene inactivation; *Nf1* OPG mice). [140, 141] *Nf1* OPG mice exhibited reduced exploratory behaviours and deficits on measures of selective and non-selective attention within the context

of intact sensorimotor abilities. [140] Consistent with these deficits, high-performance liquid chromatography revealed significantly reduced dopamine levels in the striatum of these animals. Based on parallels between attention dysfunction in the *Nf1* OPG mice and attention deficits in children with NF1, the mice were treated with 20mg/kg of methylphenidate (MPH), a commonly used intervention for the behavioral symptoms of ADHD, which blocks striatal dopamine transporters [142] and significantly increases extracellular dopamine in the striatum. [143] MPH treatment rescued the non-selective attention deficit in these mice, as did L-dopa, a precursor to dopamine that acts on the dopaminergic but not serotonergic pathway, highlighting reduced DA as the primary etiology underlying the observed attention deficits in these mice. Neurotransmitter imaging analyses using [11C]-raclopride positron-emission tomography (PET) confirmed the striatal DA defect *in vivo* and demonstrated that improved behavioral functioning was accompanied by a significant increase in striatal DA following treatment with MPH. In contrast, treatments that target neurofibromin-regulated RAS and cAMP defects, such as lovastatin, did not improve the attention deficits or PET abnormalities in these *Nf1* OPG mice.

5.0. NEUROCOGNITIVE THERAPIES IN NF1

Notwithstanding the clear cross-species differences between mice and humans, results from murine studies have provided strong evidence that cognitive deficits, at least in part, are not solely attributable to developmental abnormalities of brain structure that may be more resistant to interventions and therapy. Rather, pharmacological “correction” of these molecular abnormalities, such as aberrant RAS signaling or reduced DA, has the potential to normalize aspects of the human NF1 cognitive phenotype.

To date, only one study has evaluated the effect of stimulant medication in children with NF1. Mautner and colleagues examined the effect of MPH on 20 children with NF1 with comorbid ADHD (NF1+ADHD) in a non-randomized open-label non-controlled trial.⁵⁵ Children with ADHD alone (n = 20) were included for comparison. While on medication, parents and teachers reported an improvement in the attention span of children with NF1+ADHD. From baseline to follow-up 12 months later, parent and teacher ratings indicated significant improvements in attention, anxiety/depression, and social competence scores of children with NF1+ADHD. There was also a significant improvement on a computerized task of attention/inhibition for the NF1+ADHD group, with fewer omission (inattention) and commission (impulsivity) errors, and faster reaction times. While providing some promising results, the limited design of this study, lack of appropriate control group and the small sample size limit its interpretation and generalizability to the NF1 population. Additionally, this study exclusively investigated the effect of MPH in children with ADHD (who also had NF1) and did not investigate the efficacy of MPH as a treatment for attention and executive deficits in NF1 (regardless of ADHD status). We are currently examining the efficacy of MPH in treating sustained attention and spatial working memory impairments in children and adolescents with NF1 in a placebo-controlled, two period crossover, double-blind, Phase II clinical trial (Australian New Zealand Clinical Trials Registry Number: ACTRN12611000765921). In addition to cognitive outcome measures, a combination of functional neuroimaging techniques

(fMRI and R-fMRI) is being employed to establish whether MPH modulates functional connectivity and task-based neural activity within specific regions of interest.

To date, two clinical trials have been published on statin treatment for cognitive impairment in NF1, with variable results. [144, 145] The aim of these studies has been to improve cognitive performance by normalizing RAS activation. In the first of these studies, 62 children with NF1 were randomized to either simvastatin or placebo using a permuted block 1:1 randomization. Randomization was double-blind and the treatment period was 12 weeks. Results revealed no significant differences between the simvastatin and placebo groups on any primary outcome measure, including delayed recall of the Rey Complex Figure, a speeded cancellation test, a prism adaptation measure and the mean brain apparent diffusion coefficient (based on MRI). There were a number of weaknesses with this study, however, that limits interpretation of the results. First, the treatment period was short, with the full dose (40mg/day) only given to half the treated cohort ($n = 15$) for four weeks. The dose was lower in the other treated patients (20mg/day for 12 weeks). Second, the study was not limited to participants with a specific type of cognitive impairment. As such, children were enrolled for treatment even though they did not necessarily demonstrate impairment on a primary outcome. Third, children with very low IQ scores (as low as 48) were also included in the study, making it very difficult to compare their results to patients with normal IQ. In the other study, Acosta and colleagues conducted a Phase I trial examining the safety and tolerability of lovastatin in children with NF1. [145] Neurocognitive assessments were also performed pre-and post- treatment. Twenty-four children with NF1 were recruited for the three month study; three were treated with 20mg/day; three commenced on 20mg/day and escalated to 30mg/day after two weeks; and 18 commenced on 20mg/day and escalated to 40mg/day after two weeks. Results revealed minimal side effects and the absence of any dose-limiting toxicity. Reliable change statistics indicated significant improvements in verbal and nonverbal memory exceeding those expected from test-retest or practice effects. The authors concluded that these observations could be analogous to those observed in NF1 mice treated with lovastatin. [40] As this was a Phase I trial, however, the primary aim of the authors was safety and tolerability, not neurocognitive outcome. Study limitations included open label design, small sample size, lack of an appropriate control group and inclusion of patients without defined cognitive impairment. As such, the conclusions that can be drawn from pre-post treatment cognitive assessment are limited. There are currently a number of statin trials nearing completion that are addressing a number of the limitations of these published studies (e.g., [clinicaltrials.gov](https://clinicaltrials.gov/ct2/show/study?term=NCT00853580) identifiers NCT00853580, NCT00352599).

In addition to pharmacological treatments, there are a number of non-pharmacological interventions that could be explored in children with NF1. To the best of our knowledge, no studies examining non-pharmacological treatments for cognitive impairment have been published in the NF1 literature. Two of the most promising areas of research in populations other than NF1 (e.g., learning disability, ADHD) have been computer-based training programs for working memory and reading impairment; both of which are core features of the NF1 phenotype. Over the past few years, several computer-based working memory training programs have been developed. The most well-known of these is Cogmed; a program that includes both visuospatial and verbal working memory training tasks in which the level of difficulty adapts throughout the treatment course. Cogmed has been used in several controlled trials in children and adolescents with ADHD and has been reported to result in significant improvements in visuospatial and verbal working memory, response inhibition as well as parent ratings of working memory and attention. [146-148] Importantly, treatment effects appear to

be maintained overtime. [147, 149] A recent meta-analysis, however, has suggested that although training programs such as Cogmed have positive effects tasks that are close to those trained; there is currently only limited evidence of the generalization of working memory training on skills such as verbal and nonverbal ability, word decoding and arithmetic. [150] A feasibility study of Cogmed in NF1 is currently underway at Children's National Medical Center, Washington DC.

There is also compelling evidence that systematic and explicit instruction in phonological awareness and phonics (knowledge of letter-to-sound relationships) results in significant gains for most children with reading impairment. [151, 152] Both phonological awareness and phonics are predictors of reading ability, and importantly, there are strong data to suggest that an emphasis of phonological awareness positively influences word reading outcomes. [153] Although the benefits of phonics intervention have been recognized in the general population, the unique cognitive profile of patients with NF1 may influence the efficacy of remediation programs in children with the condition. [73] To the best of our knowledge, there are currently two studies examining reading interventions in children with NF1. The goals of the first trial are to examine the efficacy of two different training programs in poor readers with NF1 and to compare the treatment response of the NF1 group to children with a reading disability from the general population who also complete the training programs (clinicaltrials.gov identifier NCT00624234). In the second study, the efficacy of a commercially-available computer-based phonics training program is being examined in children with NF1 and phonological reading impairment (Australian New Zealand Clinical Trials Registry Number: ACTRN12611000779976). The high frequency of reading impairment in children with NF1 and the negative influence reduced reading ability has on quality of life, school achievement and peer relations, makes treatment studies such as these critical. Poor reading skills have also been associated with poorer health outcomes, decreased responsiveness to health education, less health knowledge and poorer health status. [154] As such, the importance of improving reading and literacy skills in individuals with NF1 – a progressive disorder associated with significant physical manifestations throughout the lifespan – cannot be overestimated.

CONCLUSION

Cognitive and learning impairments are the greatest cause of lifetime morbidity in individuals with NF1. The literature presented in this chapter outlines common neurocognitive and behavioral impairments, academic difficulties and developmental considerations. The goal of research into cognitive deficits in NF1 is the development of successful remediation programs to prevent the pattern of school failure that is common in children with the disorder. Currently, therapeutic intervention is likely to rely on symptomatic educational intervention. This will often involve the provision of a range of strategies to be implemented at home and in the classroom which tailor the child's learning environment to their cognitive and behavioral strengths and weaknesses. Most of these techniques, however, are not evidence-based and it is often unclear how effectively they are being implemented.

Human neuroimaging and murine studies are beginning to provide critical evidence for the pathobiological basis of NF1-related cognitive impairments. While structural abnormalities, such as an enlarged corpus callosum, have been shown to impact on cognitive performance,

they are developmental in origin and given the fundamental relationship between brain structure and function, may be difficult to reverse in childhood with pharmacological intervention. Murine studies, however, provide compelling evidence that mutation at *Nf1* results in molecular anomalies, such as RAS hyperactivation and DA abnormalities which result in specific cognitive deficits. Taken together, these preclinical studies suggest that children with NF1-associated cognitive impairments are likely to comprise a heterogeneous population of individuals with distinct molecular etiologies — but importantly, that pharmacological correction of these molecular abnormalities has the potential normalize aspects of the NF1 cognitive phenotype. Although very few treatment studies have been published in humans with NF1, there are a number of pharmacological and non-pharmacological clinical trials currently underway that aim to overcome the limitations of previous studies.

ABSTRACT

The purpose of this chapter is to provide an overview of communication disorders observed among children and adults with Neurofibromatosis type 1 (NF1). In each section, terminology, prevalence and information regarding assessment for individuals in the general population will be presented. The literature describing communication disorders observed in the population of individuals with NF1 will be reviewed. Following a review of the literature, options for speech-language assessments for individuals with NF1 will be discussed.

INTRODUCTION

The purpose of this chapter is to provide an overview of communication disorders among children and adults with neurofibromatosis type 1 (NF1). A communication disorder occurs when an individual is unable to comprehend or produce verbal, nonverbal, or graphic messages [1]. About 12 to 13% of school-aged children exhibit a communication disorder [2]. Approximately 1.5 million school-aged children receive special services for speech/language disorders annually [3]. Children with NF1 often exhibit communication disorders in the areas of voice and *resonance* [4], *articulation/phonology* [5, 6] and expressive and receptive language [4], negatively impacting communication throughout development. While some

individuals with NF1 may be unaffected, others exhibit a delay or disorder in one or multiple areas of communication. In light of this variability, all collateral areas of communicative functioning should be assessed by a speech-language pathologist.

NF1 AND MANIFESTATIONS OF THE HEAD AND NECK

NF1 is an autosomal dominant neurocutaneous disorder with a prevalence of approximately 1 in 3000 [7, 8]. NF1 is caused by mutations in the *NF1* gene on chromosome 17q11.2 [9]. Key clinical manifestations of NF1 include café-au-lait macules, axillary freckling, Lisch nodules, optic nerve pathway tumors and distinctive bone abnormalities [10]. The prognosis for individuals with NF1 is highly variable. While approximately 59% of individuals will not develop significant medical complications as a result of NF1, the remainder will develop one or more complications [11].

Studies of patients with NF1 have shown that approximately 87% of individuals experience head and neck symptoms including tumors of the eyelids/orbit and face/cheek [12]. Optic nerve gliomas are the most frequently observed intracranial tumor [13]. The impact of head and neck manifestations can be relatively benign (i.e., macrocephaly), or significant, resulting in problems with hearing, vision, eyelid motility, and facial expression [12].

Approximately 72% of individuals with NF1 experience oral manifestations including oral neurofibromas, enlarged fungiform papillae, and wide inferior alveolar canals [14]. Dysphagia may also occur [15]. Cases of patients with symptoms of NF1 and speech problems [13] or hoarseness [16] have been reported. While the etiology of speech sound disorder in this population is unknown, it has been suggested that speech problems may be secondary to neurofibromas of the tongue, pharynx or larynx [13], decreased oromotor tone [17], or motoric dysfunction [5]. It has been reported that mechanical disruptions caused by tumors cannot always account for the speech impairment observed [15].

NF1 AND VOICE DISORDERS

A voice disorder is defined as an abnormal production or absence of vocal quality, pitch, resonance or duration [1]. Voice disorders occur in <1-23% of school aged children [18-22] and 3-7% of adults [23, 24] in the general population. An assessment of voice typically follows an evaluation by an otolaryngologist to rule out or confirm the presence of laryngeal pathology. Videostroboscopy of the larynx and an assessment of respiratory functioning and flexible nasolaryngoscopy may take place [see 25]. Observation of the type of breathing employed, and measurements of *fundamental frequency*, loudness, and quality of voice may also be completed [26].

Differences in voice have been noted between populations with and without NF1. The growth of a neurofibroma can impact movement of the mechanism [27]. While neurogenic tumors of the larynx are rare, neurofibromas occurring in the aryepiglottic folds can cause hoarseness and stridor [13]. For example, Yucel and colleagues [28] found dyspnoea and coughing in a six-year-old with a plexiform neurofibroma originating in the left aryepiglottic fold.

In describing the voice of individuals with NF1, a number of terms have been used in the literature, including: *breathy* [5, 29], hoarse [4, 5, 27, 29], strained [5], creaky [5], monotone, [29], fluttering [5], having a tremor [29], or unvarying loudness [29]. Among patients with NF1, voice concerns have been reported in children [4, 27, 30] and adults [31-33]. Solot and colleagues [27] found that approximately 22% (5/23) of their group of children with NF1 exhibited hoarseness compared to none of the ten unaffected sibling controls. One child presented with a large plexiform neurofibroma under the left collarbone and exhibited impaired vocal quality and *hypernasality*. In a later study, three of nineteen preschool children (16%) were characterized as having a voice disorder [4].

The prevalence of voice disorder in individuals with NF1 is significantly higher than in the general population [18, 23, 24]. Alivuotila et al. [5] evaluated the voice quality of 62 children and adults with NF1 and 24 unaffected control participants; abnormal phonation was observed in 26 (42%) of the individuals with NF1 compared to 3 unaffected individuals (13%). Twenty-four percent of the individuals with NF1 exhibited a strained, creaky, hoarse, or breathy voice quality and were noted to have a narrower range and difficulty regulating pitch compared to unaffected control participants. It was hypothesized that individuals with NF1 exhibited problems with motor coordination of the vocal folds, resulting in concerns with pitch regulation, phonation, and harmonic structure. It was also suggested that problems with a central mechanism may account for the differences between typical and affected populations.

Other investigations of adults with NF1 found the presence of voice disorders [5, 31] characterized by an atypically loud volume (40%) [31], or a harsh or creaky voice quality [31]. To examine quality of voice, Cosyns et al. [32] studied a group of adults with NF1 and unaffected participants. All participants were nonsmokers without a history of voice disorder, and were native Dutch speakers who did not have laryngeal or pharyngeal neurofibroma. Group differences showed significantly lower vital capacity values for subjects with NF1 versus the control group. Patients with NF1 exhibited narrower frequency and intensity ranges compared to participants of the same gender in the unaffected group. No significant between-group differences were observed for *jitter*, *shimmer*, mean fundamental frequency, and pitch variation. However, both males and females with NF1 exhibited significantly lower *dysphonia* severity index scores versus unaffected individuals, suggesting that overall voice quality was poorer in patients with NF1. Results of this study corroborated the report of Alivuotila et al. [5] that there is a narrower pitch range in patients with NF1 compared to control participants.

To characterize the impact of a voice disorder on an individual's functioning, Cosyns et al. [33] analyzed the results of the Flemish Dutch version of the Voice Handicap Index (VHI) [34] completed by 30 Flemish adults with NF1 and 30 healthy subjects. The VHI asks questions designed to assess the impact of a voice disorder on a person's functional, emotional and physical functioning (e.g., "I tend to avoid groups of people because of my voice" [35]). VHI total scores were significantly higher for the individuals with NF1 compared to the control group. The authors hypothesized that rather than the elevated VHI scores for individuals with NF1 being associated with the voice disorder specifically, scores may have been related to patients living with a progressive disease throughout their lifespan.

NF1 AND RESONANCE/VELOPHARYNGEAL FUNCTIONING

Among children with communication disorders, 3-4% manifest resonance disorders [20]. A resonance disorder can be related to changes in oral or nasal cavity size or configuration, muscle contraction/relaxation, positioning of the oral structures [26], or an imbalance of oral to nasal airflow. Resonance is evaluated by perceptual or instrumental methods during examinees' production of sustained vowels, oral or nasal sounds, or sentences heavily loaded with *oral* or *nasal phonemes* (to detect the presence of hypernasality or hyponasality). Indirect assessment of velopharyngeal functioning involves the use of *nasometry* and the Simplified Nasometric Assessment Procedure (SNAP) [36]. Participants repeat sentences loaded with oral or nasal phonemes. Results yield a ratio of oral to nasal airflow (nasalance score) for each stimulus set. Nasalance scores are compared with test norms from a sample population [36]. The Zoo Passage (a passage composed of sentences containing no nasal phonemes) allows the examiner to assess if a patient can establish and maintain velopharyngeal closure during connected speech [36]. Other assessment techniques, such as the use of nasendoscopy or videofluoroscopy, allow observation of velopharyngeal functioning more directly.

Studies that have examined resonance and/or velopharyngeal functioning among individuals with NF1 indicate the presence of hypernasality and/or *velopharyngeal insufficiency* [VPI; 4, 5, 17, 31, 37-40]. Pollack and Shprintzen [39] observed mild hypernasality in four of seven children (4-13 years of age) with NF1 using multi-view videofluoroscopy and nasoendoscopy. Three exhibited mild-moderate, moderate, or severe hypernasality. VPI did not occur with structural problems of the palate, pharynx or cervical spine, suggesting that a factor other than mechanical deviations likely contributed to the hypernasality observed.

Resonance problems have been reported in 1-52% of individuals with NF1, depending on the study. Reasons for discrepant results are unknown as studies employed large age ranges of participants and did not always describe the methods used to determine the presence of a resonance disorder. Solot and colleagues [27] examined pilot data of 23 children with NF1. Five of them (ca. 22%) exhibited hypernasality, in contrast to none of the unaffected sibling controls (n=10). A large study showed that approximately 1% of 200 children with NF1 (mean age 17.4 years) exhibited velopharyngeal incompetence [38]. Ferner, Hughes and Weinman [41] examined 103 individuals with NF1 and 105 control participants between the ages of 6 and 75 years. Nineteen (19%) of the individuals with NF1 exhibited hypernasal speech compared to none of the control participants. In another report, twelve patients with NF1 (without cleft palate) were identified as having hypernasal speech [17]. Adenoidectomy (n=3), the presence of brainstem pathology (n=2), or the presence of a Chiari I malformation (n=1) were stated as possible causes of velopharyngeal insufficiency. Alivuotila and colleagues [5] found abnormal nasality in 29% (18/62) of individuals with NF1 who were 7-66 years of age. The value obtained by Alivuotila et al. [5] was lower than the values obtained by Zhang and colleagues' [52.3% (11/21)] [42] investigation involving children and adults and the study of Thompson et al. [4] showing 42% of preschool children with NF1 having abnormal resonance. Finally, spontaneous speech and oral reading samples from 33 adults with NF1 [31] showed 37% of the group (n=11) was rated as hypernasal. While some studies were limited by small sample sizes, the literature indicates that velopharyngeal insufficiency occurs among individuals with NF1.

Cosyns and colleagues [37] examined a group of 24 Flemish adults with NF1 and 16 unaffected control participants using nasometric procedures with a variety of stimulus sets. Data from the individuals with NF1 were compared with normative values and control participant data to show male participants with NF1 had significantly higher nasalance scores for oronasal and oral texts than control male participants. When individual scores were compared with normative data, 9 of 12 males and 4 of 12 females with NF1 had scores outside of normal limits (at least one standard deviation above or below the mean) on some speech tasks. Results of these studies indicate that while there is variability across investigations, most individuals with NF1 do not exhibit resonance disorders.

NF1 AND FLUENCY

With a prevalence of approximately 1% in preschool children [43, 44], and 0-1% in school-aged children [18, 43, 44], a fluency disorder is characterized by an interruption in the flow of speaking. Specifically, it is noted by an atypical rate and/or rhythm, with repetitions or *prolongations* of sounds, syllables, words and/or phrases [1] and is often accompanied by secondary behaviors such as excessive tension or struggle [45].

Fluency is typically assessed through a case history interview to obtain information concerning the history, development, and current patterns of *dysfluency*. As part of the assessment, reading and conversational speech samples are obtained in different speaking contexts (e.g., at home, work, or school) to determine speech rate, pattern and frequency of the fluency concern [45].

In a literature review by Van Borsel and Tetnowski [46], fluency was reported as a concern for many individuals with NF1 [46]. Problems with rate [27, 31] and rhythm [13, 27] have been reported as well. Cosyns et al. [30] administered a questionnaire and found that adults with NF1 experienced fluency problems either at the time of the evaluation (5.5%) or historically (3.6%). From the group of individuals who reported that they stuttered, *blocking* was reported as the most frequently-occurring fluency concern [30]. As this initial investigation did not include a formal evaluation, the exact nature of dysfluency in individuals with NF1 is unclear. Following the study using surveys, Cosyns et al. [47] examined the speech of a 49-year old male with a diagnosis of NF1 and no positive family history of dysfluency. To assess dysfluencies, several speech samples were collected including spontaneous speech, monologue, repetition of words and sentences, automatic series, and reading. Dysfluencies were most frequently-occurring in monologue and automatic series samples, with prolongations noted as the most frequently-occurring dysfluency type. The authors concluded that the nature of the prolongations observed was somewhat consistent with dysfluencies in other populations, as they occurred more frequently in content and multisyllabic words.

Finally, a larger examination of speech samples of 21 Dutch speaking adults with NF1 aged 17 to 64 years [48] showed that all participants exhibited dysfluencies during spontaneous speech and monologue conditions. Two individuals (10%) exhibited dysfluencies typical of individuals who stutter. Frequently-occurring types of dysfluencies included interjections, revisions, prolongations, and incomplete phrases. It was concluded that in general, dysfluencies observed in individuals with NF1 are not identical to stuttering.

SPEECH PRODUCTION PROBLEMS ASSOCIATED WITH NF1

A *speech sound* disorder occurs when a child exhibits impaired production of phonemes (i.e., consonants and vowels) past the age that would be expected [1]. One type of speech sound disorder is an articulation disorder, characterized by the substitution, omission, distortion, or addition of speech sounds, contributing to reduced speech intelligibility. Speech sound disorders can have phonological pattern, in which sounds in the same class are affected systematically due to an underlying rule [49]. For example, the phonological pattern of “fronting” occurs when children produce front sounds for back sounds (i.e., “cup” is produced “tup” and “go” is produced “dough”). Approximately 16% of three year olds [50] and 4% of 6-year olds [51] exhibit a speech sound disorder. In the general population, prevalence rates decrease with age [18, 51, 52], affecting approximately 1% of school-aged children and young adults [18, 53].

An assessment of speech typically takes place once children begin to combine words, at approximately 18-24 months of age. A speech evaluation is part of an overall assessment of communication functioning and includes an analysis of children’s sound inventory, and the syllable and word shapes employed [49]. Beginning at three years of age, children’s production of speech sounds in isolation, single words, and connected speech is assessed using standardized tests and informal measures. Testing is required to determine if performance is consistent with age expectations (e.g., standard scores, correctly-produced sounds, and the number, type and consistency of errors).

Estimates of the prevalence of speech sound disorders in the population of individuals with NF1 are difficult to obtain. Presently, there are only a few studies documenting the prevalence of speech sound disorders in this population. Studies are limited by small sample sizes, and/or a lack of information regarding the age of participants or the measures used to diagnose the speech sound disorder. These limitations suggest that prevalence estimates should be interpreted with caution.

Data collected through surveys [30, 54, 55] indicate that speech sound disorders occur in the population of individuals with NF1. Johnson and colleagues [54] found that compared to 5% of unaffected siblings, 60% of children with NF1 exhibited speech concerns. Cosyns and colleagues [30] found that 65% (39/60) of participants 4-61 years of age reported at least one speech problem (of any type), with 82% reporting that they were “less intelligible” to others from results of a questionnaire. Most participants experienced problems with the pronunciation of speech sounds. Stine and Adams [55] found that 55/217 (25.4%) children with NF1 (in grades 1-12) were reported to be enrolled in speech therapy, indicating the need for speech services in this population. These initial studies employed the results of self-report measures without formal testing, thus making the exact nature of speech sound disorders in this population unclear. Nevertheless, these studies underscore the idea that speech is a concern for many individuals with NF1.

Other studies have estimated the frequency of speech sound disorders for individuals with NF1 to be anywhere from 12 to 52%, depending on the population studied or the measure used to diagnose the speech problem. White and colleagues [13] found impaired speech in 19% of a group of 257 patients with NF1. Wong [56] reported that 12% of a group of 50 Chinese children with NF1 (ranging in age from 21 months to 18 years) exhibited speech problems. Noble and colleagues [57] found higher rates, with 24% (9/37) of a group of pre-school children with NF1

exhibiting a speech delay as their only developmental disability. As none of the studies described the assessments used to determine speech delay status and the last two included children who were under two years of age, these initial prevalence statistics may be an inaccurate estimate.

Riccardi [29] reported that 30-40% of individuals with NF1 exhibited speech problems [see Glass, L and Riccardi VM, unpublished data cited in 29]. Hypernasality, reduced rate, imprecise consonants, breathiness, hoarseness, monotone, tremor, and unvarying loudness were observed in their examination of 17 patients [29]. Rather than being attributed to factors related to the larynx, the etiology of the speech problems was thought to have a neurological origin. Solot and colleagues [27] reported that 48% (11/23) of children with NF1 exhibited articulation disorders, compared to only 20% (2/10) of unaffected sibling controls, suggesting that speech sound disorders are more frequent in patients with NF1 than in typically-developing children. However, as the control group exhibited higher rates of impairment than would be expected from the general population, further study is warranted. In another study, approximately 32% (6/19) of four- and five-year-old children with NF1 exhibited speech sound disorders as defined by a standard score of more than one standard deviation below the mean on the Goldman-Fristoe Test of Articulation-2 [4].

Speech sound disorders are present in adults with NF1 as well. For example, Riccardi and Eichner [58] reported that 57 (26%) of their group exhibited “definite” speech impairment, and an additional 57 (26%) were suspected to have a speech concern in an NF1 population followed in an academic clinic setting. Although no data were provided regarding the age of participants at the time of the evaluation, a significant number of individuals with NF1 (including adults) exhibited articulation concerns. Lorch and colleagues [31] found that 17% (5/30) of a group of adults with NF1 exhibited mild articulation difficulties and 40% (12/30) exhibited a fast rate of speech. Some of these studies were limited by small sample sizes, and not all of the studies described the testing methods employed. Nevertheless, results suggest that speech sound disorders occur in both children and adults with NF1 and are more frequently-occurring than would be observed in the general population.

Many early studies examining speech production problems in patients with NF1 reported the prevalence of speech sound disorders. However, more recently, researchers have been interested in describing the nature of speech impairment among individuals with NF1. Alivuotila et al. [5] found significantly more deviations in articulation by individuals affected with NF1 ($n = 62$) compared to a control group ($n = 24$). With the exception of abnormal /l/ and /d/ production, results were consistent with what patients indicated on self-report measures [30]. They demonstrate that patients experience speech problems well into adulthood, and many sound classes including stops, fricatives, nasals, liquids, and vowels are affected. To obtain more detail about the nature of speech sound errors, Cosyns et al. [6] completed a phonetic and a *phonological analysis* on the speech of 43 individuals with NF1 representing a wide age-range (7-53 years) including 14 children and 29 adults. All participants were monolingual speakers of Flemish and fulfilled NF1 diagnostic criteria. Results showed that 2 of the 14 children exhibited an incomplete *phonetic inventory*. Percent Consonants Correct (PCC) values were also reported, with children and adults exhibiting PCC values of 78-99% and 87-100%, respectively. The majority of children with NF1 exhibited a mild phonological disorder, with 4 exhibiting mild-moderate phonological disorders. Both adults and children with NF1 exhibited substitution, distortion, omission, and addition errors. Phonological patterns employed by children with NF1 included *final consonant deletion*, *epenthesis*, cluster simplification, and

devoicing. These results are consistent with cluster reduction, substitution and omission errors also observed in preschool children with NF1[4]. Cosyns et al. [6] noted that while adults were more proficient in their speech production abilities than children with NF1, it was apparent that adults with NF1 do not “grow out” of their speech sound disorders, and they continue to exhibit residual articulation errors well into adulthood. Taken together, results of the literature examining speech production skills of children with adults with NF1 suggest that a significant minority exhibit life-long difficulties with speech sound production.

EXPRESSIVE AND RECEPTIVE LANGUAGE AND INTELLIGENCE IN NF1

Language disorders occur when there are problems in comprehending (*receptive language*) and/or using (*expressive language*) spoken, written or other symbol systems [1]. Language disorders are characterized by problems with the form (i.e., morphology or syntax), content (i.e., semantics) or function (i.e., pragmatics) of verbal or written communication [1]. Approximately 13-19% [59-61] of toddlers/preschool children are considered “late-talkers”. At three years of age, late-talkers exhibit lower scores on language measures when compared to typically-developing peers [62]. The delays of most late-talkers are temporary and resolve prior to children entering school. However, for some late-talking children, the delays persist. Approximately 7.4% of kindergarten children [63] and 5% [64, 65] of school-aged children exhibit a language disorder.

A language assessment for young children (under three years of age) consists of an evaluation of overall communication functioning. Children’s symbolic play skills, comprehension, and production of language are evaluated through formal or informal methods (i.e., observation of children’s language use during play). A language sample may be analyzed to determine vocabulary size (*number of different words*) and *mean length of utterance* (MLU) in morphemes (see [66, 67] for rules for computing). MLU is used as a way of indexing the expansion of clauses [68] and average sentence length [69], and emerging language/grammatical abilities [66, 67]. Formal assessment methods involve the use of standardized tests to assess children’s general communication development (e.g., Preschool Language Scales-5th edition [70], Rossetti Infant and Toddler Language Scale [71]). As children age, standardized language tests are employed. A language disorder is diagnosed when a child obtains a score of at least one standard deviation below the mean on standardized testing or demonstrates limitations in either language comprehension or language production during spontaneous conversation. Analyzed language samples of 175-utterances in length [72] provide information about the child’s expressive morphosyntactic abilities, mean length of utterance in morphemes, and number of different words.

While articulation and voice disorders are common manifestations and recognized, most clinicians still do not associate early language impairment with NF1. In the 1980s and 1990s, much of the research examining language outcomes of individuals with NF1 was developed from the medical field, specifically neurology. Studies that suggested the presence of language delays (or verbal ability/disability) in this population originated from a body of research that was primarily interested in describing the nature of learning disabilities [e.g., 73] or the cognitive phenotype [e.g., 74]. In a few of the studies, the diagnosis of a language problem was

made following participants' poor performance on language-related subtests of neuropsychological measures, where describing language performance was not the primary focus of the study. Speech-language pathologists were frequently not included in the studies. A few studies included measures that are typically used for the identification of language problems in populations with aphasia [e.g., 31, 76]. Although the primary focus of this section concerns language outcomes for individuals with NF1, this literature was initially focused on describing the cognitive skills of individuals with NF1 (see Chapter 7). Thus, prior to the discussion of language outcomes, a brief description of the literature examining results of intelligence testing and learning disabilities is provided.

In general, individuals with NF1 exhibit lower IQ scores than those who are unaffected [41, 74, 76-80]. Scores tend to fall in the below-average to low-average range. When group means of verbal IQ and performance IQ subtests are evaluated, results are variable across studies [see 81 for a review]. Some studies have reported higher scores in verbal IQ than performance IQ [73, 82, 83], or higher scores in performance IQ than verbal IQ [79, 84]. The majority of papers, however, have shown no significant difference between verbal and performance indices [41, 55, 78, 85-87].

Learning difficulties/disabilities have been reported with a frequency of 30-65% in children with NF1 [55, 58, 73, 76, 88-91]. In general, a definition of "learning disability" refers to a discrepancy between intelligence quotients (IQ) and standard academic achievement scores, where IQ scores are higher [e.g., 55]. There is little consensus regarding the nature of learning disabilities in this population. Reasons for the discrepant results across studies include variable comparison groups, differences in the methodologies used, failure of studies to control for IQ [92], or differences in what authors consider a "discrepancy" in a learning disability [93].

Early studies proposed that nonverbal learning disabilities were prevalent in NF1 [73] and more frequent than language-based/verbal learning disability [55]. However, more recently investigations have indicated that language-based learning disabilities occur as well [see 81]. Language problems have been identified in the NF1 population with specific deficits in the areas of reading [31, 41, 76, 82, 94-96], spelling [31, 89, 94, 95], decoding and phonological awareness skills [96], vocabulary [96], naming [74, 79], and written language [31, 77, 82].

Eliason [73] was one of the earliest authors to report language deficits in the population of children with NF1, reporting that 30% (8/23) of children with NF1 referred to a learning disorders clinic exhibited language problems. Eldridge et al. [79] found almost identical rates of spoken language disorder between children and adults with and without NF1, with 2/13 children and adults with NF1 and 3/13 unaffected siblings exhibiting a possible spoken language disorder. Eldridge et al. [79] indicated that perhaps developmental disabilities occurred more frequently than would be expected in the unaffected group of participants, which may account for the elevated rates of language impairment in those without NF1. Others have reported lower expressive vocabulary abilities in children with NF1 [aged 6;6 to 13;7 (years; months)] compared to unaffected siblings [aged 7;11 to 16;4] [74]. Mazzocco et al. [76] assessed verbal and nonverbal performance of 19 pairs of children (with and without NF1, 6-16 years of age) using several neuropsychological measures. Children with NF1 obtained significantly lower scores than the unaffected group in the areas of word definitions, expressive vocabulary, total written language and contextual vocabulary, receptive syntactic language, reasoning, phonological memory, and phoneme segmentation. No significant between-group differences emerged from several neuropsychological measures. Dilts et al. [77] examined the receptive and expressive language of nineteen children with NF1 (aged 6-17 years) and a group

of unaffected siblings as part of a study designed to establish a behavioral phenotype of NF1. Approximately 58% of the group of children with NF1 failed the CELF screening test. Of the children who failed screening, it was noted that 26% of the sample exhibited delays in both expressive and receptive language. Approximately 32% of the group exhibited delays in expressive language alone. Consistent with the findings of Mazzocco and colleagues [76], Dilts et al. [77] concluded that children with NF1 had significant verbal deficits. In the adult population, 13% and 40% of individuals with NF1 exhibit delays in reading and writing, respectively [31]. Results of the studies suggest that even though IQ may be close to equivalent in populations with and without NF1, language disorders are a significant, although not always recognized, concern in childhood.

Many of the previous investigations examined children who were 6-16 years of age. In an effort to better identify children with NF1 who are at-risk for later problems, researchers became interested in examining the language outcomes of a younger group of children with NF1 from 7 months to 8 years of age [97, 98]. Results of these studies varied depending on the measures used to assess the presence or absence of a language delay. Nevertheless, studies reported concerns with language early in life. At 21-30 months of age, longest sentences (as measured by parent report on the MacArthur Communicative Development Inventory) of children with NF1 are not significantly different from age-matched controls, although children with NF1 exhibit poorer global language ability [98]. At 3-5 years of age, language delays occur in 53% of children, with receptive language delays in approximately 37%, and expressive language delay in 37% [4]. Leguis et al. [83] examined children in three different age ranges, including children from 17 months-4 years of age, 4-6 years of age, and 6-16 years of age. In the youngest group, they found that 6 out of 7 children (86%) exhibited language delays, specifically in the area of morphology. At 4-6 years of age, most children exhibited higher verbal intelligence scores than performance intelligence scores. In the oldest age group, while many obtained below-average scores, more than half of the group obtained total intelligence quotients in the average range. The authors reported that because many children exhibited language delays early in development, it would be useful to follow a group of children to determine which ones develop learning disabilities later in life.

Soucy et al. [97] examined a much smaller age range of children with NF1 (aged 7-months to 8-years) using the Parents' Evaluation of Developmental Status: Developmental Milestones (PEDS). The PEDS is a screening tool used to determine the presence of a range of developmental disorders. Children with NF1 were noted to present with delays in 24% and 22%, in receptive and expressive language, respectively. These results indicate that language delays occur very early in development for a significant minority of children with NF1, supporting the referral of children with NF1 to speech-language pathologists prior to their second year [98]. As the sensitivity of the PEDS in predicting language problems in children two years later is poor [99], it is possible that many children with language delays were not correctly identified following test screening, and the values obtained from this study could be an underrepresentation of the language delays in children with NF1. Nevertheless, results of these studies suggest that language impairment frequently occurs in the NF1 population.

While the exact etiology of language impairment in NF1 is unknown, it has been postulated that differences in brain morphology may account for the delays observed [95, 100]. One study found an association between planum temporale surface area asymmetry and IQ-based reading comprehension for individuals with NF1 [100]. Another study found that an extra right hemisphere inferior frontal gyrus in patients with NF1 was associated with better performance

on language-related measures (e.g., phonological fluency, verbal knowledge, reading, spelling, and verbal memory) [95]. Finally, the presence of minor brain malformations (e.g., hypothalamic hamartomas, malformations of cortical development) among individuals with NF1 has been associated with lower scores in intelligence, reading, mathematics and spelling [101]. Researchers sought to determine if reading difficulties in children and adolescents with NF1 were related to the pattern and extent of activation during phonological processing [102]. Individuals with NF1 exhibited more activation in the inferior frontal cortex during auditory phonological processing compared to control participants, suggesting that activity in the inferior frontal cortex may play a role in language deficits in this population. Large corpus callosum index scores have also been associated with poorer intelligence, reading, verbal memory, and executive functioning [103]. Future research may provide additional information on the relationship between anatomy, function and behavior. For example, the use of resting state functional connectivity [see 104] has been proposed as viable outcome measure for evaluating the use of pharmacological agents in the treatment of developmental processes in NF1 [e.g., 105].

Results of these accumulated studies over the last 25 years suggest that while many individuals with NF1 may exhibit language concerns, many individuals are also unaffected. As a result of this research, careful screening and monitoring of the language skills of this population should take place, with follow-up intervention as needed. Potential assessment procedures will be discussed in detail below.

GAPS AND OPPORTUNITIES

The studies presented in this chapter have a number of limitations. The majority of the studies employed large age ranges of participants, limiting the generalization of study results. As younger children with language delays may be slow to develop, they may have the potential to acquire language normally without intervention (i.e., “late-talkers”). In contrast, older children with language delays may have language-based learning disabilities, and display residual language concerns following intervention. Combining children with these two different etiologies into one group prevents researchers from obtaining a clear picture of the language disorder in this population. As the profile of a language disorder changes over time, it is important that studies group children of a similar age range and use measures that are appropriate for examining language performance of that age range.

Second, it was noted that the majority of studies employed language subtests of IQ measures rather than language-specific measures. In speech-language pathology, language subtests of neuropsychological measures are generally not employed to diagnose the presence or absence of a language disorder. Current research on specific language impairment and other developmental language disorders do not use verbal IQ in the development of their behavioral phenotypes. Neuropsychological measures may have an insufficient number of items to assess a given area. Children may exhibit a delay in an area of language that is not captured through neuropsychological testing, but can be identified through language sample analysis or formal language testing. Therefore, while it is important that speech-language pathologists use the information from neuropsychological testing to guide clinical practice, it should be used as a foundation for other testing in the field of speech-language pathology.

Finally, rather than including age-matched control children, unaffected siblings were frequently included in the studies. As communication skills change over time, age-matched, unaffected controls would make for a more informative comparison group. As previous authors have suggested that outcomes may be influenced by the patient's experience of living with NF1, another appropriate comparison group may be individuals living with a different progressive disease.

To date, the etiology of communication disorders in NF1 remains unclear. Some studies have suggested that functional or physiological characteristics limit speech production [13, 17]. Others have suggested that differences in brain morphology can account for the language delays [95, 100]. Two studies that examined the nature of speech sound errors in individuals with NF1 noted the presence of phonological patterns [4, 6]. As phonological disorders are cognitive-linguistic in nature, mechanical factors alone cannot explain the speech sound disorder in this group. From a review of the literature, at this stage there does not appear to be a coherent linguistic phenotype of speech in NF1 [106]. Important moderators of NF1 manifestations that have yet to be determined may place children at risk for language delays. Additional research is needed to determine the etiology of language impairment in this group, and it is imperative that language studies incorporate specific measures rather than subtests of other psychological assessments.

ASSESSMENT

In light of the previous literature review, it is apparent that children and adults with NF1 have an elevated risk for difficulties in a number of areas of communication functioning including voice, resonance, fluency, articulation, and language. Currently, there is a paucity of research describing appropriate assessment protocols specifically addressing speech and language concerns for individuals with NF1. This section provides guidelines regarding speech-language assessment for this population.

From 21-months of age, children with NF1 exhibit problems with language development [98]. By three to five years of age, children with NF1 are more likely to exhibit speech sound disorders and language delays than the general population [4]. As resources may be limited for families with children with disabilities and attendance at speech-language evaluations may place an additional burden on families who already have many medical appointments, the use of screening measures is highly recommended. Options for screening include the MacArthur-Bates Communicative Development Inventories [107] (for younger children), or the Clinical Evaluation of Language Fundamentals-Screening Test [108] (for older children). Follow-up testing is warranted following a failed screening. A referral to a speech-language pathologist is also warranted at 24 months of age if the child produces fewer than 50 words or no two-word combinations, *and* if parents are concerned about their child's speech, language or hearing or if the child has had six or more episodes of otitis media [109].

At two years of age, children's speech and language should be examined to assess vocabulary (Number of Different Words), MLU and production of early-developing sounds. Measures should be compared with normative data to determine if the child is within normal limits or significantly different from typically developing children. While the child's speech

and language status may be quite low given the child's chronological age, voice and fluency should also be monitored.

As children enter preschool, an assessment of general communication skills should take place. Speech sound production should be assessed. Standardized tests of articulation or phonology (such as the Goldman-Fristoe Test of Articulation-2 [110] or the Bankson-Bernthal Test of Phonology [111]) can be employed. To assess expressive and receptive language, omnibus language testing should be administered (using standardized measures), and a language sample should be collected. As children are at risk for hearing loss (as are any unaffected children), they should undergo a hearing screening to ensure that their hearing is within normal limits on the day of testing. An oral mechanism exam should also take place to determine if oral-motor structure and function is within normal limits for the purpose of speech and to assess any differences in oral anatomy. Fluency and voice should be informally assessed during conversation.

For school-aged children with NF1, fluency, voice/resonance, speech, and expressive and receptive language should be assessed. As in the preschool years, standardized tests can be administered to assess speech sound development, expressive and receptive language. A language sample analysis should be completed, as some children with NF1 may be able to perform adequately on omnibus language tests but still present with deficiencies in their expressive language that are uncovered in their spontaneous conversations [112]. Results of subtests of neuropsychological testing can provide information regarding how children use language for problem-solving, as well as inform clinicians as to what additional (and more specific) testing should be completed to obtain a clear picture of a child's language skills.

Language samples can identify strengths and weaknesses in the areas of sentence length and complexity (including MLU), vocabulary/number of different words, morphology, and syntax. In addition to *morphosyntax*, other areas that are not assessed by neuropsychological testing include narrative comprehension and narrative production. These areas can be evaluated through measures such as the Test of Narrative Language [113]. Additionally, as children with NF1 age, other areas of language functioning, such as sentence and paragraph comprehension, nonliteral language use, inferencing, and the ability to abstract meaning from context should be assessed.

CONCLUSION

The purpose of this chapter was to present a literature review of the communication disorders observed in the population of children and adults with NF1. It should be recognized that the speech and language characteristics within this population are extremely variable. Some individuals will not present with any significant limitations and others will exhibit difficulties in one or multiple areas. From a review of the literature, individuals with NF1 often exhibit concerns with voice, resonance, fluency, articulation, and expressive and receptive language more frequently than the general population. A summary of the findings is presented in Appendix 1. The reason for the variability is unclear; the severity of NF1 symptoms does not necessarily predict severity of the communication difficulties as a straightforward association. Communication disorders are a component of the cognitive phenotype for NF1.

As children with NF1 are at-risk for communication disorders, age-appropriate screening measures should be implemented in routine management. Minimally, communication development should be assessed when children are two and then again at least once in the preschool years to prevent negative academic and social outcomes. Children with central nervous system anomalies (i.e., optic pathway tumors, hydrocephalus, posterior fossa tumors, or intracranial vascular abnormalities) require closer surveillance for communication disorders. Upon the identification of a communication disorder, follow-up intervention and re-assessments should take place, as needed.

APPENDIX 1: PREVALENCE OF COMMUNICATION DISORDERS OBSERVED IN THE POPULATION OF INDIVIDUALS WITH NF1 AND THE GENERAL POPULATION (IN PERCENT)

Disorder Area	Age	Expected Range	Observed Rate for Individuals with NF1	
			Range	Median
Voice	P	7% [21]	16% [4]	16%
	S	<1-23 ¹ % [18-22]	22 ² -55% [5, 27]	39%
	A	3-7% ³ [23, 24]	27-40% [5, 31]	35%
Resonance	P		1-42% [4, 38]	22%
	S	3-4% ⁴ [20]	1-52% [5, 27, 38, 41, 42]	22%
	A		1-52% [5, 31, 38, 42]	27%
Fluency	P	1% [43, 44]		
	S	<1-1% [18, 43, 44]		
	A	0-1% [43, 44]	10% [48]	10%
Speech Sound	P	16% ⁵ [50]	12-32% [4, 13, 56, 57]	23%
	S	1-4% [18, 51]	12-19% [13, 56]	16%
	A	1% ⁶ [53]	19-52% [13, 58]	36%
Language	P	13-19% [59-61]	0-86% [4, 83, 97, 98]	24%
	S	7% [63]	0-58% [73, 76, 77, 79, 114]	40%
	A	5% [64]	40% [31]	40%
Reading	P			
	S	2-13% [115, 116]		
	A	3% ⁷ [117]	13% [31]	

P = Preschool, S = School-age, A = Adult

Values in the table are rounded to the nearest percent.

¹ Percent of children exhibiting chronic hoarseness.

² Age of the children was unknown.

³ Participants reported having a current voice disorder.

⁴ Children with communication disorders who exhibited a resonance concern in grades 6-8.

⁵ Prevalence of speech sound disorder in 3 year old children.

⁶ Estimate of residual speech disorder prevalence in college freshman.

⁷ Prevalence of self-reported learning disability.

APPENDIX 2: GLOSSARY OF TERMS

Articulation: The production of speech sounds.

Blocking: An inappropriate cessation of air or voice that may co-occur with discontinued movement of the articulators.

Breathy: Voice produced during lax approximation of the vocal folds.

Devoicing: Production of voiceless phoneme in place of a voiced phoneme (e.g., “*dok*” instead of “*dog*”).

Dysfluency: An inability to exhibit effortless speech production.

Dysphonia: An alteration in normal phonation.

Expressive Language: A communication disorder in which there are problems with the production of language in the verbal or written modality.

Epenthesis: The addition of a segment in a word (e.g., “*belu*” instead of “*blue*”).

Final consonant deletion: Deletion of the final consonant in a word (e.g., “*go*” instead of “*goat*”).

Fundamental frequency: The number of vocal fold vibratory cycles per second.

Hypernasality: Excessive nasal resonance during the production of vowels, vocalic consonants, liquids and glides.

Jitter: Fundamental frequency perturbation.

Mean length of utterance in morphemes: The total number of morphemes in a language sample divided by the number of utterances.

Morphosyntax: Following the development of theoretical linguistics, it is a term used to acknowledge the relationship between children’s development of morphology and syntax. English-speaking children who are older than 4 years of age and are still omitting *third person singular*, *regular* and *irregular past tense*, *auxiliary* and *copular present tense* forms at a high rate may be delayed in their development of morphosyntax. Speakers acquiring languages that are structurally different from English will display deficits consistent with the typology of their native language.

Nasal phonemes: Phonemes requiring only nasal airflow for production (e.g., *m*, *n*, or “*ing*”).

Nasometry: Use of a computer-based instrument to determine an individual’s nasalance score.

Number of different words: The total number of different (types) of words contained in a 50-utterance language sample.

Oral phonemes: Phonemes requiring only oral airflow for production (e.g., *b*, *p*, *s*, *f*, *g*).

Phoneme: The smallest unit of sound used to form meaningful contrasts between utterances.

Phonetic inventory: An individual’s speech sound repertoire.

Phonology: The science of speech sounds and sound patterns.

Phonological analysis: The evaluation and scoring of an individual’s speech for the purpose of identifying patterns of speech sound errors.

Prolongation: A core behavior or stuttering in which a sound or airflow continues simultaneously to the cessation of the movement of the articulators.

Receptive Language: Comprehension or understanding of language.

Resonance (disorder): An imbalance of oral and nasal airflow.

Shimmer: A measurement of loudness perturbation.

Velopharyngeal insufficiency: An anatomical or structural defect preventing appropriate closure of the velopharyngeal port.

Chapter 114

CHILDREN WITH NEUROFIBROMATOSIS TYPE 1: FUNCTIONING IN THE CLASSROOM

ABSTRACT

Neurofibromatosis Type 1 (NF1) is a multisystem disorder, and cognitive impairment is its most common complication in childhood (Hyman, Gill, Shores, Steinberg, Joy, Gibikote, & North, 2003). Although patients with NF1 are at risk for significant clinical illnesses, most patients are only mildly affected and live healthy and productive lives (North, 2000). Most research in NF1 to date has been focused on defining the physical and cognitive deficits based on standardized testing, with little emphasis on their functional correlates (Gilboa, Rosenblum, Fattal-Valevski, & Josman, 2010b).

Evidently, student engagement in the classroom reflects, in a large part, self regulation skills which are influenced by temperament and higher order cognitive executive function processes. In particular, sustained attention, which comprises both task-oriented attention and low impulsivity, predicts academic and behavioral adjustment (Pagani, Fitzpatrick, & Parent, 2012).

The purpose of the present chapter is to identify predictors associated with school participation in a sample of children with NF1. A unique feature of this work is the examination of children's participation across different classroom activity components such as handwriting and cognitive skills, such as attention and executive function. Each of these classroom activities may require a unique set of functional skills to meet specific demands. Findings and insights presented in this chapter may help clarify the important factors supporting effective engagement by children with NF1 in school programs.

The chapter describes the functional problems of children with NF1 in the classroom according to the *International Classification of Functioning, Disability and Health*–

Children and Youth version (ICF-CY) (WHO, 2007). The chapter includes current literature on NF1, using the framework provided by the ICF-CY in highlighting the holistic evaluation and interpretation of disabilities. In the first part it presents the ICF-CY (WHO, 2007) conceptual model, defines the term 'ecological validity' and details regarding two ecologically valid assessment tools (Virtual Classroom and functional questionnaire).

The chapter subsequently describes the functional academic profile of children with NF1 from three points of view: attention profile, academic skills in relation to executive profile and handwriting performance. The set of tasks composing each activity provides a useful indication of the factors that may underlie functional participation of children with NF1 in the classroom context. The chapter illustrates the functional profile with a case study and we conclude the chapter with suggestions for further research.

INTRODUCTION

The International Classification of Functioning, Disability and Health—Children and Youth version (ICF-CY) (WHO, 2007)

The World Health Organization's International Classification of Functioning, Disability and Health (ICF) (WHO, 2001) is the most recently developed framework for describing and classifying an individual's health and health-related states. The International Classification of Functioning, Disability and Health – Children and Youth version (ICF-CY) published in 2007 (WHO, 2007) is derived from the ICF (WHO, 2001). The ICF-CY provides a scientific basis for understanding and studying the health and health-related states of children and young people by establishing a common language to facilitate communication and the transfer of information across health professions.

CONCEPTUAL FRAMEWORK OF THE ICF-CY

The goal of the ICF-CY framework is to classify all aspects of health and health-related states. The current framework is a logical approach to viewing diverse aspects of health from biological, individual, and social perspectives (Stucki, Ewert, & Cieza, 2003). The information is organized into two parts: (a) functioning and disability, and (b) contextual factors (WHO, 2001). Each of these parts is further categorized into two components. The functioning and disability section includes: (a) body structures and body functions, and (b) activity and participation. The contextual factors represent the background of an individual's life and include: (a) environmental factors, and (b) personal factors. The main components of the ICF-CY model are summarized in Figure 1.

'Functioning' and 'disability' serve as two contrasting terms encompassing human functioning and disabling conditions. 'Functioning' relates to the successful completion of major day-to-day activities across a broad range of expected roles in daily life. 'Disability' has been described as an inability to perform these critical daily living activities in the normal range as a result of impairment (WHO, 2001).

Figure 1. International Classification of Functioning, Disability and Health (ICF). (Adapted from WHO, 2001).

Body structures and functions represent the different body systems and their specific roles. The activity and participation component refers to an individual's performance of activities, either physical or mental, that are associated with all aspects of life. The successful completion of activity and participation involves the integration of body structures and functions in a purposeful manner within various contexts, including the physical, social, and attitudinal environments (WHO, 2001).

The environmental component within the contextual part comprises the physical, social and attitudinal aspects of the environment in which people live and conduct their lives. Personal factors constitute features related to the individual, such as gender, age, fitness, coping abilities, and social background that could play a role in disability at any level (WHO, 2001). The ICF-CY model encourages an interactive view of functioning and disability, in which both personal and environmental factors are often interrelated in a dynamic way (Cramm, Aiken, & Stewart, 2012).

THE ECOLOGICAL VALIDITY OF COGNITIVE ASSESSMENTS TOOLS

In its general sense, ecological validity is the degree to which results obtained in controlled experimental conditions are related to those obtained in naturalistic environments. In the context of neuropsychological testing, ecological validity refers to the degree to which test performance corresponds to real world performance, or the individual's ability to generalize results of controlled experiments to naturally occurring events (Gioia & Isquith, 2004). Validity does not apply to the test itself, but to the inferences that are drawn from the test. Therefore, tests that have adequate diagnostic validity do not necessarily have adequate ecological validity (Chaytor & Schmitter-Edgecombe, 2003).

Evaluating the ecological validity of neuropsychological tests has become an increasingly important topic over the past decade (Chaytor & Schmitter-Edgecombe, 2003). With the development of brain-imaging techniques, neuropsychological testing has progressed. From facilitating brain pathology diagnosis the aims of the tests have changed to allow the description of functional strengths and weaknesses (Lezak, Howieson, Bigler, & Tranel, 2012), the

prediction of everyday functioning, and the need for intervention and support in the natural environment (Chaytor & Schmitter-Edgecombe, 2003). It is suggested that a parallel shift from “traditional” validity considerations to ecological validity considerations need to follow (Gioia & Isquith, 2004).

Clinical predictions are made as to how people will most likely perform in natural settings in relation to their poor performance on certain tests. However, these predictions are seldom based on any strong scientific evidence. In a review of the literature on ecological validity of neuropsychological tests, it was found that in most cases the magnitude of relationship was only moderate ($r=0.30$) and many neuropsychological tests were not related to measures of outcome (Chaytor & Schmitter-Edgecombe, 2003).

When neuropsychological tests are developed and applied to identify or quantify deficits, traditional validity (e.g., construct validity) is paramount and ecological validity may be of little concern (Gioia & Isquith, 2004). Implicit in the definition of ecological validity as its concept is applied to innovative assessment tools, is, that performance on a test predicts some aspect of the child’s functioning on a day-to-day basis (Chaytor & Schmitter-Edgecombe, 2003; Gilboa et al., 2010b).

EVALUATION OF COGNITIVE AND FUNCTIONAL PROBLEMS

Constant advances in test development has resulted in increased knowledge of cognitive problems in all disorders, yet many functional areas remain beyond the reach of formal assessment tools. As remediation needs to be based on what is occurring in the classroom and in daily life, in greater detail than a neuropsychological test alone can provide (Chaytor & Schmitter-Edgecombe, 2003), understanding of these real world functional deficits, is essential in setting out remediation guidelines (Lezak et al., 2012).

Despite the broad range of deficits present in children with NF1, research into functional assessment remains largely unexplored. The use of neuropsychological testing to understand the cognitive deficits of children with NF1 is somewhat limited. There is a lack of studies that can provide vital information on the impact of cognitive and other deficits in daily life (Gilboa et al., 2010b).

The Use of Virtual Reality Environments and Questionnaires to Evaluate Day-to-Day Cognitive Functioning

During the past decade, ongoing advances in computer graphics, software, and hardware design have refined medical simulators to offer life-like replications of medical and surgical procedures in a variety of medical specialties (Willaert, Aggarwal, Van Herzeele, Cheshire, & Vermassen, 2012).

Virtual Reality (VR)

Virtual Reality (VR) technology delivers something beyond the scope of currently available computerized flat screen assessments, as it can be used to immerse and test a user within a dynamic, three-dimensional, ecologically valid stimulus environment under conditions

more similar to the challenges of the “real” world (Rizzo, Bowerly, Buckwalter, Klimchuk, Mitura, & Parsons, 2006). VR technology offers the option to produce and distribute identical “standard” simulation environments in which an individual’s performance can be measured. Digital scenarios allow normative data to be accumulated for performance comparisons needed for assessment/diagnosis and for treatment/rehabilitation purposes. The capacity of the VR to create dynamic, immersive three-dimensional stimulus environments that record all behavioral responses, offers assessment options that in traditional assessment methods are simply not available (Josman, Milika Ben-Chaim, Friedrich, & Weiss, 2008). It even has advantages over real-world behavioral observations, as it provides a controlled stimulus environment where cognitive challenges can be presented along with the precise delivery and control of distracting auditory and visual stimuli, and real-world responses can be objectively measured (Rizzo et al., 2006).

The last decade has been an enormously exciting time for neuropsychological VR applications. Research has now evolved to a point where VR is regarded as an invaluable tool in examining the neural correlates of everyday cognition (Penn, Rose, & Johnson, 2009). The degree of stimulus control and sensitivity of monitoring afforded by VR is also a significant advantage when examining subtle behaviors, such as head movements in children with ADHD (Parsons, Bowerly, Buckwalter, & Rizzo, 2007).

Functional Questionnaires

Functional questionnaires provide an additional means of understanding and expanding the cognitive profile of children with NF1. These functional questionnaires describe difficulties in day-to-day functioning in the type of detail that a single standard score on a psychometric measure is unable to provide. They also provide a measure of more than a single sample of performance (unlike neuropsychological tasks) and take into account performance in less “ideal” situations where normal distractions are present and compensatory strategies may be utilized (Fingerhut, Madill, Darrah, Hodge, & Warren, 2002; Verkerk, Wolf, Louwers, Meester-Delver, & Nollet, 2006).

Parents and teachers possess a wealth of information about children’s behavior in those settings that are directly relevant to an understanding of function (Gioia & Isquith, 2004). Parent’s and teachers’ functional questionnaires provide an additional means of understanding and expanding the cognitive profile of children in general and specifically children with NF1. For example, The Behavior Rating Inventory for Executive Functioning (BRIEF) (Gioia, Isquith, Guy, & Kenworthy, 2000) was developed with ecological validity in mind. The impetus for the BRIEF came from the need to more efficiently and systematically capture information about manifestations of executive function difficulties in children’s everyday behaviors at home, in school, and in their communities (Gioia & Isquith, 2004). This functional questionnaire describes difficulties in day-to-day functioning, provides a measure of more than a single sample of performance, and takes into account performance in less “ideal” situations where normal distractions are present and compensatory strategies may be utilized. It was designed to question the parents about their child’s everyday life situations while the examiner reaches his conclusions regarding his EF (Fingerhut et al., 2002; Verkerk et al., 2006).

Describing the Attention Deficit profile of Children with NF1 Using a Virtual Classroom Environment (Gilboa, Rosenblum, Fattal-Valevski, Toledano-Alhadeff, Rizzo, & Josman, 2011a; Gilboa, Rosenblum, Fattal-Valevski, Toledano-Alhadeff, Rizzo, & Josman, 2011b)

The Virtual Classroom (VC) (Rizzo et al., 2006), a head-mounted display (HMD) immersive VR system, was developed for the assessment of attention skills using a virtual environment that simulates a classroom. Recent findings have provided support for the construct validity of this VC in children with ADHD (Adams, Finn, Moes, Flannery, & Rizzo, 2009; Parsons et al., 2007; Rizzo et al., 2006). Concurrent validity has also been demonstrated by correlating VC results with other widely used ADHD assessment tools (Adams et al., 2009; Parsons et al., 2007; Rizzo et al., 2006). These studies suggest that the VC has good potential for controlled performance assessment within an ecologically valid environment and appears to parse out significant effects due to the presence of distraction stimuli (Adams et al., 2009; Parsons et al., 2007; Rizzo et al., 2006).

The research version of the VC scenario consists of a standard rectangular classroom environment containing desks, a female teacher, a blackboard across the front wall, a side wall with a large window, and on the opposite wall, two doorways (Figure 2). The scenario runs on a standard PC with a head mounted display with onboard orientation tracking.

Figure 2. The virtual classroom.

The task required the child to tap the left mouse button as quickly and accurately as possible, using their dominant hand when the digit sequence “37” appeared on the VC blackboard. The stimuli remained on the screen for 150 ms with a fixed interstimulus interval of 1350 ms. Participants were instructed to withhold their responses to any other sequence of digits. The test lasted 10 minutes (5 identical blocks of 2 minutes) during which 400 stimuli (100 of them were “37” sequences) were presented accompanied by 20 distractors (e.g., pure audio [classroom noises], pure visual [paper airplane flying across the visual field] and mixed audiovisual [a car “rumbling” by a window, a person walking into the classroom with hall sounds when the door opened]). Distractors were each displayed for 5 seconds and identically presented in the entire sample.

The participants' reaction patterns were recorded and documented using four measures: 1. *Total correct hits*- the ability to correctly identify 100 targets out of 400 stimuli during 10 minutes (correct and incorrect hits, measured as raw score out of 100), 2. The number of

commission errors. 3. *Reaction time* was measured in milliseconds and 4. *Head movements* were captured and quantified from the inertial tracking system. This is used to sense head orientation as the input signal. Head movements are sensed by this system and quantified in three orientation axes.

The study was the first to use the VC environment to assess attention processes in NF1 children. The objectives of the study were (1) to compare the performance of children with NF1 and the control group in the VC and (2) to assess the utility of the VC to detect attention deficits in a sample of NF1 children in comparison with a widely used ADHD screen questionnaire.

Participants included 29 children diagnosed with NF1 according to the NIH criteria (9 males, 20 females; mean age 12.2 ± 2.5). The control group consisted of 25 Typically Developing (TD) children matched to the study group by gender and age (7 males, 18 females; mean age 12.2 ± 2.6). The groups did not significantly differ in mean age, school year, gender and handedness. As expected, the IQ score of the NF1 group (13.0 ± 98.9) was lower than the control group (12.3 ± 109.3). However, this gap did not differ significantly. In addition to the VC the Conners' Parent Rating Scales-Revised: Long (CPRS-R:L) (Conners, 1997) was administered.

The results from the assessment of the VC task, showed that the performance of the NF1 group was significantly lower than the controls on *total correct hits* (mean 74.37 ± 21.64 vs. 87.40 ± 10.48 ; $p < 0.01$) and the number of *commission errors* (mean 20.27 ± 23.03 vs. 5.87 ± 5.34 ; $p < 0.01$). The NF1 group responded correctly to fewer targets and committed more errors than the control group on the entire task and in each 2 minute block. No significant differences were found on *reaction time*. NF1 participants were also not significantly more hyperactive compared to controls on all three measures of *head movement* (captured from the tracking system that is part of the HMD) (Table 1).

The number of targets correctly identified by the two groups' declined as a function of the time, (Figure 3). However, the pattern of the commission errors group was stable and didn't significantly change as a function of time (Figure 4).

For the NF1 group, a significant negative correlation was found between the VC's total correct hit and the cognitive problems/inattention clinical scale of the CPRS-R: L ($r = -0.42$, $p < 0.05$). Thus, more correct hits negatively correlated with lower scores (i.e.: better attention skills) on this measure.

The difficulty to correctly identify 100 targets out of 400 stimuli during 10 minutes can be explained by a deficit in sustained attention (Lavine, Sibert, Gokturk, & Dickens, 2002) and/or switching attention. Support for this hypothesis is evident in the present study, as more correct hits, significantly correlated negatively with the cognitive problems/inattention clinical scale of the CPRS-R: L. The linear decreasing pattern of attention as exemplified in figure 3 clearly suggests difficulties in continuous attention. However, since both groups showed a trend towards declining performance over time, this result may be related to a "fatigue effect".

A significant difference was also found between the NF1 and control group on the number of commission errors, with NF1 children producing more errors than controls. The NF1 group responded less accurately to the stimulus due to impulsive responses in the absence of a target. This impulsivity pattern, characteristic of the NF1 group, was found to be stable as a function of time.

Figure 3. Total correct hits in relation to time.

Figure 4. Commission errors in relation to time.

No significant difference was found between the groups on the *reaction time* to targets. From the results of the present study we conclude that such differences in processing speed (the response time between stimulus and reaction) as suggested in children with ADHD (Parsons et al., 2007), were not found in children with NF1. Also, no significant differences were observed in all three measures of *head movements* in participants with NF1 as compared to the TD control group. These findings lead to the conclusion that the attention deficit profile of children with NF1 does not include increased overall hyperactivity.

To conclude, the VC results support the hypothesis that NF1 is marked by inattention (omission errors) and impulsivity (commission errors). The VC appears to be a sensitive and ecologically valid assessment tool for use in the diagnosis of attention deficit in children with NF1.

The EF of Children with NF1 and its Relation to their Academic Skills

A study that explored the impact of NF1 on school performance clearly demonstrates that children with NF1 are severely affected. At least 75% of the children with NF1 have one or more learning disabilities in technical reading, comprehensive reading, spelling, or mathematics. In comparison with the average population, children with NF1 attended more special education classes with an odd ratio of 4:1; repeated a grade in their school career (17% vs 1.9%), and received remedial teaching for learning problems (85% vs 15%) (Krab, Aarsen, de Goede-Bolder, Catsman-Berrevoets, Arts, Moll, & Elgersma, 2008).

Executive functions (EF) are a set of interrelated cognitive and behavioral skills that activate and govern our conscious perceptions, feelings, thoughts and actions, constituting a collection of “co-conductors” (McCloskey, Perkins, & Van Divner, 2008). It leads the individual to act in a purposeful, organized, strategic, self-regulated goal-directed manner. EF can be divided into discreet sub-skills that include setting and managing goals, planning, inhibition and dealing with diverse elements, shifting among cognitive and affective sets, organization, working memory and meta-cognition (Ylvisaker & Feeney, 2002). EF is a key metacognitive skill underpinning successful goal directed behavior, and is linked to educational attainment (St Clair-Thompson & Gathercole, 2006).

Recently, efforts have been made to develop more specific tests of executive ability, representing a departure from tests that have discriminative validity for diagnostic purposes, to ecologically valid assessments, in which test results are able to predict functional abilities relevant to real world functioning (Wood & Lioffi, 2006). In a study that aimed to examine the extent to which ecologically valid measures of EF are useful in predicting school functioning, two types of EF assessments were used:

- 1) Performance-based assessment: A standardized test that shows promise to be ecologically valid, to test EF performance among children, the Behavioral Assessment of the Dysexecutive Syndrome for Children (BADS-C) (Emslie, Wilson, Burden, Nimmo-Smith, & Wlson, 2003).
- 2) Everyday functional assessment: A questionnaire that evaluates everyday demands of EF in the natural setting, the Behavioral Rating Inventory of Executive Functions (BRIEF) (Gioia, Isquik, Guy, & Kenworthy, 2000).

In order to look at school performance, we used the Academic Competence Evaluation Scales (ACES) (DiPerna & Elliott, 2000) and teacher's questionnaire, as an outcome measure. A child's overall level of academic competence is dependent upon a set of five dynamic constructs which include academic skills, study skills, interpersonal skills, engagement, and motivation. These five dynamic constructs can be categorized as either Academic Skills or Academic Enablers (DiPierna & Elliott, 1999). Academic skills refer to the child's mastering of specific reading and language arts, mathematics and critical thinking skills. The other four constructs of motivation, engagement, study skills and interpersonal skills, constitute the Academic Enablers.

Twenty-nine children with NF1 and 27 age-and-gender-matched controls (age 8-16) were examined. The performance of the NF1 group was significantly lower on the *Water* ($F(1, 57) = 4.85, p < .05, d = .57$) and the *Key Search* ($F(1, 58) = 5.47, p < .05, d = .47$) subtests of the BADS-C. After controlling for estimated IQ, significant differences were found between the groups

on the reported *Working Memory* ($F(1, 42) = 11.08, p < .001, d = 1.03$) and the *Plan/Organize* ($F(1, 42) = 6.49, p < .05, d = .67$) scales as well as the *Meta-cognition Index* ($F(1, 42) = 4.21, p < .05, d = .82$) and the *Global Executive Composite* ($F(1, 41) = 7.21, p < .05, d = .81$) of the BRIEF, and on the *Academic Skills* scale of the ACES ($F(1, 26) = 4.86, p < .05, d = 1.96$). Varieties of significant correlations were found between the BADS-C's subtests and the BRIEF's scales and the teacher's reports on the ACES. Significant predictive models were generated for BADS-C, BRIEF and ACES scores.

The data from this study, in combination with other studies (Mazzocco, Turner, & Denckla, 1995; Payne, Hyman, Shores, & North, 2011; Rowbotham, Pit-ten Cate, Sonuga-Barke, & Huijbregts, 2009) strongly support the existence of a specific profile of executive dysfunction in the NF1 group of children, beyond the decrease in IQ. The executive dysfunction profile of children with NF1 is characterized by a combination of deficits in the metacognitive skills of planning, problem solving, and working memory. Significant predictive models were generated for BADS-C, BRIEF and ACES scores, suggest that this EF profile is related to difficulties that children with NF1 experience at school in the areas of academic and social functions.

The Activity of Handwriting

Handwriting is an important task learned during early school years. A high proportion of a child's school day is dedicated to writing assignments, an essential ingredient for success at school (McHale & Cermak, 1992). Writing is indispensable for participation in school activities, such as taking notes and tests, doing homework, and writing papers (Weintraub, Drory-Asayag, Dekel, Jakobovits, & Parush, 2007). This complex perceptual-motor skill requires adequate performance in visual-motor coordination, motor planning, cognitive/perceptual skills, and tactile and kinesthetic sensitivities (Maeland, 1992). There is evidence of deficits in cognitive/perceptual skills (Hyman *et al.*, 2003), motor skills (Billingsley, Slopis, Swank, Jackson, & Moore, 2003; Hofman, Harris, Bryan, & Denckla, 1994; Levine, Materek, Abel, O'Donnell, & Cutting, 2006) and visual-motor integration skills (Levine *et al.*, 2006), skills in children with NF1 which may interfere with handwriting competency.

Very little research on the nature and cause of writing difficulties is available (Rosenblum, Parush, & Weiss, 2003) despite the fact that writing production tends to be the most neurologically vulnerable language modality (Lorch, Ferner, Golding, & Whurrd, 1999). Non-proficient handwriting appears to have considerable apparent consequences on a child's academic performance and emotional well-being and persists longer than other symptoms (Lorch, 1995).

The Handwriting Performance of Children with NF1 (Gilboa, Josman, Fattal-Valevski, Toledano-Alhadeff, & Rosenblum, 2010a)

The handwriting performance of children with NF1 was evaluated following the developmental model as describe by Feder & Majnemer (2009). The evaluation included multilevel developmental and functional assessments, starting with the ability to copy geometric forms using the Beery-Buktenica Developmental Test of Visual-Motor Integration

(VMI) (Beery, 2004) and was followed by two common functional everyday writing tasks: paragraph copying and free style written text. Previous studies indicated that the VMI is a significant predictor of handwriting legibility on a copying task (Daly, Kelley, & Krauss, 2003) and evidence of significant impairment on VMI score was previously seen among children with NF1 (Hyman et al., 2003). Therefore the relationship between the VMI standardized score and the subsequent writing measures were examined.

In our study, the children's writing performance were evaluated at three levels in two writing tasks: the mechanical aspects of both writing tasks were evaluated with a Computerized Penmanship Evaluation Tool (CompPET), including an electronic writing tablet (digitizer) (Rosenblum et al., 2003), that enabled collection of spatial, temporal, and pressure data of the child's writing *process*. The CompPET, has been demonstrated to be highly valuable with children with specific learning disability (Rosenblum, Weiss, & Parush, 2004). Then, *the product's legibility* of the copying task was evaluated by administering the Hebrew Handwriting Evaluation (HHE), (Erez & Parush, 1999) a standardized, reliable and valid handwriting assessment for the Hebrew language. Finally, the handwriting product *content* of free style writing was assessed with the Six Trait Writing Method (Spandel, 2004).

The objectives were to analyze the process and product of handwriting and the relationship between visual-motor integration and features of handwriting that characterize performance of children with NF1 in comparison to those of TD children.

A total of 60 children were tested: The study group consisted of 30 children diagnosed with NF1 according to the NIH criteria (9 males, 21 females; mean age 12y 3mo, $\pm$ 2y 6mo; range 8y -16y 8mo). The control group consisted of 30 TD children matched to the study group by gender and age (mean age 12y 4mo, $\pm$ SD 2y 5mo; range 8y 5mo-16y 4mo). All participants used the Hebrew language as their primary means of verbal and written communication.

We found a significant difference between the groups for the VMI standardized scores ($t(1, 58) = -3.17, p < 0.01$). The NF1 ($M=86.93 \pm 17.17$) children performed worse than the TD ($M=101.90 \pm 14.74$) group. For the study group, significant correlation was established between the VMI and the free style writing task's organization ($r=0.41, p<0.05$).

When considering the handwriting mechanical process results, surprisingly, no significant differences were found between children with NF1 and TD in temporal measures for writing velocity on-paper and in-air time per stroke (CompPET variables) as well as for pen pressure. This finding may stem from the fact that the groups included a female majority (21 girls versus 9 boys). However, a significant difference was established between the groups in the measure of mean stroke height within the copying task ($F(1,57)=5.18, p<0.05$).

Significant correlations were also found between the mean velocity, total duration per stroke and in-air time per stroke and the number of unrecognizable letters on the handwriting product ranging from .37 to .58. Children with NF1, who exhibited more unrecognizable letters, wrote faster, spent considerably more total time on the task and spent greater in-air time. In-air writing occurred with significantly greater frequency for poor writers than for the proficient writers in most handwriting tasks. This is highly indicative of EF such as planning (Rosenblum et al., 2003), visual spatial organization (Rosenblum & Livneh-Zirinski, 2008) and the perceptual aspect of the motor act related to writing (Werner, Rosenblum, Bar-On, Heinik, & Korczyn, 2006) such as motor memory for letter formation or difficulty in visualizing letters needed and to form them rapidly (Rosenblum & Livneh-Zirinski, 2008).

The performance of the children with NF1 in the spatial arrangement of their handwriting product (HHE variable) ($F(1,57)=4.24, p<0.05$) as well as in the level of the content for ideas,

organization, voice, word choice, sentence fluency and conventions (Six-Trait Writing Model variables), was significantly poorer than for the children without NF1 ($F(6, 52) = 3.42, p < 0.01$). Significant negative correlations were found between the number of letters erased and/or overwritten on the copying task and two factors of the Six-Trait Writing Model: Ideas ($r = -0.422, p < 0.05$) and organization ($r = -0.52, p < 0.01$) and the total score ($r = -0.37, p < 0.05$) for the free style writing task.

To summarize, evaluation of NF1 children with both process and product measures, provides an impression of their handwriting performance. Handwriting product was found to be poorer among children with NF1 in terms of content and spatial arrangement. These difficulties come to fruition in the different tasks, from figure copying to impaired handwriting.

We provide a case study to describe a functional profile of a child with NF1 in the classroom. A summary report of the assessment process highlighted his difficulties in EF and writing, and the goals for the intervention are illustrated.

Jonathan: Case Study

Jonathan, a boy aged 7 years and 4 months, is a grade one student. He has been attending special education preschool for the last 4 years, and now attends a special education class in a public school. Jonathan is the second son in his family of five children, who live in an urban area. His family is of moderate-low socioeconomic status.

Jonathan's birth was a regular delivery following a normal pregnancy. As an infant, his motor and language performance were delayed for his chronological age. At the age of 6 he was tested by a psychologist. His intellectual functioning was found to be at the poor range of the norm ($IQ = 83$), with a significant gap between language (94) to performance (73) intelligence. By the age of 3 he was diagnosed as a case of NF1 by a pediatrician.

He was referred to the Occupational Therapy service in his school because he was experiencing frequent handwriting problems and clumsiness. Jonathan's teacher reported that his achievements in reading, understanding and mathematic were adequate as compared to the other students in his class.

His parents are concerned mainly about his extensive writing difficulties, as will be detailed later in this profile; they also describe his difficulties in organizing materials. His parents perceived his academic performance to be lower than appropriate for his age. He avoided daily learning activities like homework and when he experienced difficulty, he immediately gave up.

Referral to Occupational Therapy

The referral was made by his teacher. During a preliminary interview with the Occupational therapist, Jonathan's teacher mentioned the following concerns:

- Jonathan presents difficulties in effectively using his learning tools including notebooks, pencil case and bag.
- Jonathan presents difficulties in organizing the text he writes within lines; the size of the letters is too big.
- During class, Jonathan copies text from the blackboard in an imprecise way: omits letters, connecting words and lines.

- Legibility of both letters and digits are poor.
- Jonathan is unfocused and appears to be preoccupied by other things.

Assessment tools:

- The following assessment tools were used:
- Background questionnaire for collecting data regarding Jonathan's functioning and reasons for referral.
- Interview with Jonathan's parents to assess his level of participation in all performance domains and to help choose appropriate tools for him.
- Observation in Jonathan's class and an interview with his teacher to evaluate his level of participation at school.
- The BRIEF parent and teacher questionnaire to Assess executive function behaviors in the school and home environments.
- The developmental test of Visual-Motor integration- Revised to obtain deeper sensory-motor evaluation.

Major Findings and Discussion

The occupational therapists impression based on the performance evaluations was as follows:

Executive Function

Jonathan performed activities in the right sequence but displayed difficulty in flexibility: moving from one stage to another. He completed a task quickly and with carelessness and did not check his performance. He did not initiate a discussion, but responded to the questions that were asked. He showed difficulty in inhibiting his reactions when require to do so and to solve problems with minimal mediation.

The BRIEF questionnaire reveals that Jonathan's parents indicated major difficulties in inhibition, shifting, organizing of materials, monitoring and behavioral regulation (see figure 5). Jonathan's teacher also indicated major difficulties in inhibition, emotional control, planning and organization of materials, monitoring, as well as behavioral regulation, metacognition and the global executive composite (see Figure 6).

Attention

Jonathan did not wait until the teacher finished talking, resulting in her often having to stop him from starting a task. Since he didn't listen to instructions, Jonathan asked the teacher for many cues (he said that he did not remember the instructions) and used them to complete the tasks. His ability to use cues such as "What do you need to do next?" were very helpful.

Figure 5. Jonathan's parent profile on the BRIEF.

Figure 6. Jonathan's teacher profile on the BRIEF.

Writing

Jonathan displayed difficulties in spatial organization that negatively affected his writing legibility. For example, he wrote the text in an inappropriate place and did not use the margins.

Jonathan's writing difficulties also stem from a motor basis. He had difficulty generating appropriate muscle force when using objects that required gentle force (like pencil). He displayed difficulty in isolating movements of the wrist and put inconsistent pressure on writing tools.

On the Beery test, Jonathan received lower scores than age appropriate, both in the motor and visuomotor sections. Jonathan's score on the visual perception subtest of the Beery was age appropriate.

Emotionally, Jonathan has the ability to interact properly with adults and peers and has good internal motivation to perform whatever is required. He has a low sense of competence regarding his performance. He repeatedly said "I did not understand "or "I did it badly".

Recommendations

On the basis of the results of the evaluation, occupational therapy intervention was recommended. It was recommended that Jonathan receive 10 45-minute individual sessions of occupational therapy intervention, once a week.

Occupational therapy intervention goals are as follows:

Focus on functional treatment goals for meaningful occupations that Jonathan's parents and teachers noted during interviews. Activities that restricted typical participation included Jonathan's difficulties to complete handwriting assignments in a satisfactory way, his refusal to do homework and his difficulties in operating his writing tools.

Focus on Jonathan's emotional and executive deficits as follows:

- analyzing, together with Jonathan's parents and teacher, how difficulties in his attention and executive skills (inhibition, shifting, monitoring planning and organizing) and emotional factors limit the above occupations.
- consulting and coaching Jonathan's parents and teachers, in order to teach them strategies to help with the following goals: (1) help Jonathan to be more attentive while receiving instructions and performing tasks independently; (2) reduce external and internal distracters; (3) enable Jonathan to use self inhibition during class to help him follow instructions; (4) gradually enable Jonathan to use these strategies on his own.

This case study was provided by Michal Tsadok-Cohen and Yafit Gilboa.

CONCLUSION

This chapter identified specific functional problems that are significantly associated with difficulties in achieving successful participation in different school activities for children with NF1. The problem profile includes special deficits in sustaining attention, impulsivity, and low academic achievements that are associated with EF deficits and poor handwriting in terms of content and spatial arrangement.

Findings reported in this study do not imply a causal relationship between predictors and outcome. However, they can be used as a guide to help clinicians prioritize their clinical reasoning. The results strongly support an important assumption of the ICF-CY classification Model (WHO, 2007) and the current trends in rehabilitation toward more reliance on functional measurement rather than clinical diagnostic data to plan for children's participation in mainstream school programs (Pagani et al., 2012).

The results also identify possible pathways of influence associated with limited and full participation outcomes that should be considered during such intervention planning. For example, information about children's sustained attention and handwriting capabilities, may serve as a primary indicator to identify those who are at higher risk for limited participation at school.

Future research should aim to evaluate the participation of children with NF1 in various activities using tools that have high real-world validity and focus on the functional implications of the problems. Future research will contribute to a better understanding of the abilities and disabilities of children with NF1 in their functioning at school and at home. This knowledge would lead to increased identification of problems for planning intervention methods to satisfy the needs of this unique population, and to truly improve their quality of life; interventions that would focus on making a difference to the everyday experiences of individuals with NF1 and their families. Future research will link between understanding real-life implications and brain functioning and may also improve the understanding of the underlining mechanisms.

AN ESSENTIAL GUIDE TO CYTOGENETICS

EDITORS: Naomi Norris and Carmen Miller

SERIES: Genetics – Research and Issues

BOOK DESCRIPTION: *An Essential Guide to Cytogenetics* explores the use of cytogenetic data for studies of frogs as well as the insights that hypotheses of phylogenetic relationships have added to this issue. The authors provide an overview of PcP190 satellite DNA, sex chromosome systems and B chromosomes found in Anura.

SOFTCOVER ISBN: 978-1-53613-370-7

RETAIL PRICE: \$95

RESISTIN: STRUCTURE, FUNCTION AND ROLE IN DISEASE

EDITOR: Gerald Maldonado

SERIES: Biochemistry Research Trends

BOOK DESCRIPTION: *Resistin: Structure, Function and Role in Disease* opens by discussing resistin's therapeutic properties. Because evidence appears to suggest that resistin is a proinflammatory cytokine, resistin may impact metabolic disease.

SOFTCOVER ISBN: 978-1-53614-543-4

RETAIL PRICE: \$95
